MOTOR WINDING FAULT DETECTION CIRCUITS AND METHODS TO DETECT MOTOR WINDING FAULTS

FIELD OF THE DISCLOSURE

This disclosure relates generally to motor fault detection, and, more particularly, to motor winding fault detection circuits and methods to detect motor winding faults.

BACKGROUND

In a three-phase motor, a winding fault occurs when a portion of insulation surrounding individual windings wears down and a short circuit occurs between conductors. A winding fault effectively reduces the number of turns in the affected phase of the three-phase motor, which can unbalance the motor, reduce the performance of the motor, and/or damage the motor.

SUMMARY

Motor winding fault detection circuits and methods to detect motor winding faults are disclosed. An example motor winding fault detection circuit includes a positive sequence voltage calculator, a positive sequence current calculator, an interpolator, a negative sequence voltage calculator, and a fault detector. The positive sequence voltage calculator calculates a positive sequence voltage value for a three-phase motor. The positive sequence current calculator calculates a positive sequence current value for the three-phase motor. The interpolator calculates an expected negative sequence voltage value based on the positive sequence voltage value, the positive sequence current value, and measured characteristics of the three-phase motor. The negative sequence voltage calculator calculates a measured negative sequence voltage value for the three-phase motor. The fault detector detects that a winding fault exists in the three-phase motor when a difference between the expected negative sequence voltage value and the measured negative sequence voltage value satisfies a threshold.

A disclosed example method includes calculating a positive sequence voltage value for a three-phase motor, calculating a positive sequence current value for the three-phase motor, and calculating an expected negative sequence voltage value based on the positive sequence voltage value, the positive sequence current value, and measured characteristics of the three-phase motor. The example method also includes calculating a measured negative sequence voltage value for the three-phase motor, and detecting that a winding fault exists in the three-phase motor when a difference between the expected negative sequence voltage value and the measured negative sequence voltage value satisfies a threshold.

A disclosed example fault detection circuit includes a first Clarke transformer, a positive sequence voltage calculator, a negative sequence voltage calculator, a second Clarke transformer, a positive sequence current calculator, an interpolator, a first subtractor, a second subtractor, an amplitude calculator, and a fault detector. The first Clarke transformer has three-phase voltage signals as a first input and has an alpha voltage signal as a first output and a beta voltage signal as a second output. The positive sequence voltage calculator has the alpha voltage signal as a second input and the beta voltage signal as a third input, and has a positive sequence voltage value as a third output. The negative sequence voltage calculator has the alpha voltage signal as a fourth

2

input and the beta voltage signal as a fifth input, and has a direct negative sequence voltage value as a fourth output and a quadrature negative sequence voltage value as a fifth output. The second Clarke transformer has three-phase current signals as a sixth input and has an alpha current signal as a sixth output and a beta current signal as a seventh output. The positive sequence current calculator has the alpha current signal as a seventh input and the beta current signal as an eighth input, and has a positive sequence current value as an eighth output. The interpolator has the positive sequence voltage value as a ninth input, the positive sequence current value as a tenth input, and a baseline table as an eleventh input, the interpolator to generate, based on training data stored in the baseline table, the positive sequence voltage value, and the positive sequence current value, an expected direct negative sequence voltage value as a ninth output and an expected quadrature negative sequence voltage value as a tenth output. The first subtractor has the direct negative sequence voltage value as a twelfth input and the expected direct negative sequence voltage value as a thirteenth input, the first subtractor to determine a first difference value between the direct negative sequence voltage value and the expected direct negative sequence voltage value as an eleventh output. The second subtractor has the quadrature negative sequence voltage value as a fourteenth input and the expected quadrature negative sequence voltage value as a fifteenth input, the second subtractor to determine a second difference value between the quadrature negative sequence voltage value and the expected quadrature negative sequence voltage value as a twelfth output. The amplitude calculator has the first difference value as a sixteenth input and the second difference value as a seventeenth input, the amplitude calculator to output an amplitude of the first difference value and the second difference value as a thirteenth output. The fault detector has the amplitude as an eighteenth input and to output a fault detection signal as a fourteenth output when the amplitude satisfies a threshold.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a block diagram of a three-phase motor control device including an example winding fault detection circuit constructed in accordance with the teachings of this disclosure.

FIG. 2 is a block diagram of another three-phase motor control device including an example winding fault detection circuit constructed in accordance with the teachings of this disclosure.

FIG. 3 is a block diagram of a three-phase motor connected to an example winding fault detection circuit constructed in accordance with the teachings of this disclosure.

FIG. 4 illustrates example time domain signals that may be observed in the phase windings of the three-phase motors of FIGS. 1, 2, and/or 3.

FIGS. 5-7 illustrate example positive sequence, negative sequence, and zero sequence signals that may be calculated from the example time domain signal of FIG. 2.

FIG. 8 illustrates an example relationship between a positive sequence voltage magnitude, a positive sequence current magnitude, and a negative sequence voltage for the three-phase motors of FIGS. 1 and/or 2.

FIG. 9 is a block diagram of an example winding fault detection circuit constructed in accordance with the teachings of this disclosure to detect an winding fault in a wye-connected three-phase motor.

FIG. 10 is a block diagram of an example winding fault detection circuit constructed in accordance with the teach-

ings of this disclosure to detect an winding fault in a delta-connected three-phase motor.

FIG. 11 illustrates a more detailed block diagram of the example positive sequence voltage magnitude calculator of FIGS. 9 and 10.

FIGS. 12-15 illustrate example signals that are generated within the example positive sequence voltage magnitude calculator of FIGS. 9, 10 and 11 while calculating a positive sequence voltage magnitude value for a three-phase motor.

FIG. 16 illustrates a more detailed block diagram of the example positive sequence current magnitude calculator of FIGS. 9 and 10.

FIGS. 17-20 illustrate example signals that are generated within the example positive sequence current magnitude calculator of FIGS. 9, 10, and/or 16 while calculating a positive sequence voltage magnitude value for a three-phase motor.

FIG. 21 illustrates a more detailed block diagram of the example negative sequence voltage calculator of FIGS. 9 and 10.

FIGS. 22-25 illustrate example signals that are generated within the example positive sequence voltage magnitude calculator of FIGS. 9, 10, and/or 21 while calculating a positive sequence voltage magnitude value for a three-phase motor.

FIG. 26 illustrates a more detailed block diagram of the example data acquisition controller of FIGS. 9 and 10.

FIG. 27 is an example state machine representative of logic that may be implemented by the fault detection circuits of FIGS. 9 and/or 10 during a training phase of the fault detection circuits to store a set of training negative sequence voltage values corresponding to combinations of training positive sequence voltage magnitude values and training positive sequence current magnitude values.

FIG. 28 illustrates an example set of training negative sequence voltage values corresponding to combinations of training positive sequence voltage magnitude values and training positive sequence current magnitude values that may be stored by the example learner of FIGS. 9 and/or 10 while implementing the state machine of FIG. 27 during a training phase of the fault detection circuits.

FIG. 29 is an example state machine representative of logic that may be implemented by the fault detection circuits of FIGS. 9 and/or 10 during a protection phase to detect an winding fault in a motor.

FIG. 30 illustrates an example operating point space including a set of negative sequence voltage values.

FIG. 31A-31B is a flowchart representative of example machine readable instructions which may be executed to implement the example fault detection circuits of FIGS. 9 and/or 10 to conduct a training phase to store a set of training negative sequence voltage values corresponding to combinations of training positive sequence voltage magnitude values and training positive sequence current magnitude values.

FIG. 32A-32B is a flowchart representative of example machine readable instructions which may be executed to implement the example fault detection circuits of FIGS. 9 and/or 10 to conduct a training phase to calculate weights for an equation to estimate expected negative sequence voltage values based on combinations of positive sequence voltage magnitude values and positive sequence current magnitude values.

FIG. 33A-33B is a flowchart representative of example machine readable instructions which may be executed to implement the example fault detection circuits of FIGS. 9 and/or 10 to detect an winding fault in a motor during a

protection phase based on a set of negative sequence voltage values corresponding to combinations of training positive sequence voltage magnitude values and training positive sequence current magnitude values.

FIG. 34A-34B is a flowchart representative of example machine readable instructions which may be executed to implement the example fault detection circuits of FIGS. 9 and/or 10 to detect an winding fault in a motor during a protection phase using an equation to estimate expected negative sequence voltage values based on combinations of positive sequence voltage magnitude values and positive sequence current magnitude values.

FIG. 35A-35E is a flowchart representative of example machine readable instructions which may be executed by the example fault detection circuits of FIGS. 9 and/or 10 to measure a positive sequence voltage magnitude value, a positive sequence current magnitude value, and a negative sequence voltage value.

FIG. 36 is a flowchart representative of example machine readable instructions which may be executed to implement the example data acquisition controller of FIGS. 9, 10, and 26 to control measurement of positive sequence voltage magnitude values, a positive sequence current magnitude values, and a negative sequence voltage values.

FIG. 37 is a block diagram of an example test apparatus including the example winding fault detection circuit of FIGS. 9 and/or 10 to test times to detect winding faults in a motor.

FIG. 38 illustrates example time periods required by the example winding fault detection circuit in the test apparatus of FIG. 37 to detect an winding fault in a motor following simulation of the winding fault in the motor.

FIG. 39 illustrates example phase voltages of an example three-phase motor before, during, and after an example winding fault is simulated in the example test apparatus of FIG. 37.

FIG. 40 illustrates example an example positive phase sequence, an example negative phase sequence, and an example zero phase sequence representative of the phase voltages of FIG. 39 before, during, and after the simulated winding fault in the example test apparatus of FIG. 37.

FIGS. 41-44 illustrate example negative sequence voltages at selected motor speeds and motor loads performed using the test apparatus of FIG. 37.

FIG. 45 is a block diagram of an example processor platform capable of executing the instructions of FIGS. 31A-31B, 32A-32B, 33A-33B, 34A-34B, 35A-35E, and 36 to implement the apparatus disclosed in FIGS. 9, 11, 16, 21, and 26.

FIG. 46 is a block diagram of another example processor platform capable of executing the instructions of FIGS. 31A-31B, 32A-32B, 33A-33B, 34A-34B, 35A-35E, and 36 to implement the apparatus disclosed in FIGS. 10, 11, 16, 21, and 26.

The figures are not to scale. Wherever appropriate, the same reference numbers will be used throughout the drawing(s) and accompanying written description to refer to the same or like parts.

DETAILED DESCRIPTION

When a motor experiences a turn-to-turn stator fault, the impedance of the phase leg on which the fault occurred will be reduced. If the motor is driven by a three-phase inverter in current mode, the control loop will compensate for the impedance change by applying less voltage to the faulty phase leg to keep the currents in balance. However, less

voltage will be required to sustain a given current in the phase leg that is experiencing the fault, and the voltages will consequently go out of balance.

Three-phase motors are driven using a combination of three electrical signals having different phases. In a three-phase system, the signal components can be converted into a “positive sequence” (e.g., forward rotating), “negative sequence” (e.g., reverse rotating), and a “zero sequence” (e.g., common or shared) component. When a winding fault occurs in a three-phase motor, the primary positive sequence component is diminished, while negative sequence and/or zero sequence current components are increased. Although the presence of negative sequence and/or zero sequence current components may be good indicators of a winding fault, real-world three-phase systems are rarely (if ever) perfectly balanced. As a result, a certain amount of positive sequence and/or zero sequence current components exist.

An out-of-balance condition can be detected by a method known as sequence analysis, in which the three phase voltages are converted into the positive sequence component, the negative sequence component, and the zero sequence component. In an ideal (i.e., perfectly balanced) forward rotating system, the negative sequence and zero sequence components are zero. However, if the system is slightly out of balance, as in real-world motors, the positive sequence component will dominate, but small amounts of the negative sequence and/or zero sequence components will exist.

If the motor is healthy (i.e., no winding faults) and forward rotating, the positive sequence component will dominate, and the negative and zero sequences will be negligible. When a winding fault occurs, the positive sequence component magnitude will decrease, and the negative sequence component and/or the zero sequence component increase. In a Y-connected motor, there is no zero sequence current component and only the negative sequence component will increase.

Example methods and apparatus disclosed herein distinguish negative sequence components that are intrinsic to a particular motor and negative sequence components indicative of a winding fault.

Example methods and apparatus disclosed herein receive as inputs two phase current inputs and three phase voltage (or pulse width modulated (PWM) duty cycle) signals. Disclosed example methods and apparatus do not require a priori knowledge of machine parameters or field orientation information for the motor. Disclosed example methods and apparatus can be implemented separately from the motor, motor control circuitry, and/or motor power circuitry, and can be used to monitor electric machines at any power level. Additionally or alternatively, example methods and apparatus disclosed herein may be implemented by a motor control device, a power device, and/or a motor protection device, where the example methods and apparatus have access to the control signals or phase voltage and have access to the phase currents.

In real-world motors, construction asymmetries and non-uniformities in sensor gain can result in a motor producing negative sequence voltage components even when there are no winding faults in the motor. Disclosed example methods and apparatus establish a baseline across multiple speeds and/or loads for an individual motor drive system under protection of a fault detection circuit. Disclosed example methods and apparatus indicate or identify a fault when a measured negative sequence deviates from an expected negative sequence value determined from the baseline val-

ues. The negative sequence value, and deviations from the negative sequence values of a healthy motor, are functions of speed and load.

FIG. 1 is a block diagram of a three-phase motor control device **100** including an example fault detection circuit **102**. The example motor control device **100** of FIG. 1 receives input power **104** and generates three-phase power signals **106a**, **106b**, **106c** to drive a three-phase motor **108**. In the example of FIG. 1, the three-phase motor control device **100** is a three-phase inverter.

In addition to the fault detection circuit **102**, the example three-phase motor control device **100** includes a motor controller **110**, gate drivers **112** that drive an H-bridge **114** (e.g., transistor gates in the H-bridge), a current meter **116**, and a communications interface **118**.

The example gate drivers **112** convert PWM signals **120a-120c** to gate control signals **122a-122c**. The example H-bridge **114** includes three H-bridges that are respectively controlled by the gate control signals **122a-122c** to generate the three-phase power signals **106a-106c**. The example gate drivers **112** may be a conventional gate driver and/or the example H-bridge **114** may be a conventional H-bridge.

The example motor controller **110** generates the PWM signals **120a-120c** based on a desired motor speed. The motor controller **110** receives three-phase current measurements **124a-124c** corresponding to the three phases of the motor **108**. The three-phase current measurements **124a-124c** are measured by the current meter **116** and fed back to the motor controller **110**, which adjusts the PWM signals **120a-120c** (e.g., the pulse widths) to attempt to have balanced currents in the motor **108**. The example current meter **116** measures the currents using voltage drop measurements **126a-126c**, in which the current meter **116** divides a measured voltage difference by a known resistance value over which the voltage difference is measured.

In combination, the example motor controller **110**, the example gate drivers **112**, the example H-bridge **114**, and the example current meter **116** implement a PWM DC-to-AC three-phase inverter.

The example fault detection circuit **102** of FIG. 1 detects winding faults, such as inter-turn winding faults, in the motor **108** based on the PWM signals **120a-120c** and the current measurements **124a-124c**. When the fault detection circuit **102** detects a winding fault, the example fault detection circuit **102** communicates the detection of the fault to the motor controller **110** via the communications interface **118**, which can take appropriate action such as powering down the motor and/or generating an alert to a person responsible for the operation of the motor **108**. The example communications interface **118** may also be used to configure the gate drivers **112**. Example implementations of the fault detection circuit **102** are described below with reference to FIGS. 9-36.

FIG. 2 is a block diagram of another three-phase motor control device **200** to control the example motor **108** of FIG. 1. The example motor control device **200** of FIG. 2 includes another example fault detection circuit **202**.

In contrast with the fault detection circuit **102** of FIG. 1, the example fault detection circuit **202** of FIG. 2 is implemented in a motor controller **204** (instead of separately from the motor controller **110** as in FIG. 1). The example motor controller **204** also includes a feedback controller **206** and PWM generators **208a**, **208b**, **208c**. The feedback controller **206** receives the current measurements **124a-124c** from the current meter and generates the PWM signals **120a-120c** via the PWM generators **208a**, **208b**, **208c** to control the motor **108**. The example three-phase motor control device **200** also

includes the gate drivers **112** (e.g., which receives the PWM signals **120a-120c** and generates the gate control signals **122a-122c**), the H-bridge **114** (e.g., which receives the gate control signals **122a-122c** and generates the three-phase power signals **106a-106c**), the current meter **116**, the communications interface **118**, and the voltage drop measurements **126a-126c**.

FIG. **3** is a block diagram of a fault detection device **300** including an example fault detection circuit **302**. The example fault detection device **300** of FIG. **3** is separate from any motor control circuitry for the motor **108**, and includes a signal meter **304** to measure voltages **306a-306c** and currents **308a-308c** of the three-phase power signals **106a-106c** that drive the motor **108**. The example fault detection device **300** includes the communications interface **118** of FIGS. **1** and/or **2**.

The example signal meter **312** measures the voltages **306a-306c** and/or the currents **308a-308c**, and provides measured voltage signals **310a-310c** and/or measured current signals **312a-312c** to the fault detection circuit **310**. As explained in more detail below, the signal meter **304** may provide the three measured voltage signals **310a-310c** and two of the measured current signals **312a-312c** (e.g., in a wye-connected motor) or provide two of the measured voltage signals **310a-310c** and the three current signals **312a-312c** (e.g., in a delta-connected motor).

FIG. **4** illustrates example time domain components **402**, **404**, **406** that may be observed in the phase windings of the three-phase motors **108** of FIGS. **1**, **2**, and/or **3**. The example time domain components **402-406** correspond to the phase power signals **106a-106c** (e.g., the voltages of the phase power signals **106a-106c** and/or the currents of the phase power signals **106a-106c**).

FIG. **5** illustrates example positive sequence components **502**, **504**, **506** that may be calculated from the example time domain components **402-406** of FIG. **4**. FIG. **6** illustrates an example negative sequence components **602**, **604**, **606** that may be calculated from the example time domain components **402-406** of FIG. **4**. FIG. **7** illustrates example a zero sequence component **702** that may be calculated from the example time domain components **402-406** of FIG. **4**.

The example positive sequence components **502-506**, the example negative sequence components **602-606**, and the example zero sequence component **702** are representative of an example motor that is non-ideal but healthy (e.g., does not have any winding faults). For instance, while the negative sequence components **602-606** are typically zero in an ideal motor, non-ideal motors have small negative sequence components due to small variations in geometry or resistance between the different phases. Therefore, the example fault detection circuits **102**, **202**, and **300** of FIGS. **1-3** do not rely on the mere existence of the negative sequence components **602-606** to detect winding faults. Instead, the example fault detection circuits **102**, **202**, and **300** measure and account for the presence of the negative sequence components **602-606**, which may be unique to the specific motor **108** being protected.

FIG. **8** illustrates an example relationship **800** between a positive sequence voltage magnitude **802**, a positive sequence current magnitude **804**, and a negative sequence voltage **806** for the three-phase motor **108** of FIGS. **1-3**. In the example of FIG. **8**, the value of the negative sequence voltage **806** in the relationship **800** is dependent on a combination of the value of the positive sequence voltage magnitude **802** and the value of the positive sequence current magnitude **804**.

The example relationship **800** partially characterizes the three-phase motor **108** for use in subsequent detection of winding faults in the three-phase motor **108**. By varying the speed of the three-phase motor **108** and/or by varying a load driven by the three-phase motor **108** during a training phase, the example fault detection circuits **102**, **202**, **300** of FIGS. **1-3** may determine the relationship **800**. The example fault detection circuits **102**, **202**, **300** then use a relationship for the particular motor **108**, such as the relationship **800**, to detect winding faults by comparing an expected negative sequence voltage **806** (determined from the relationship **800**) to a negative sequence component value that is measured or observed during operation of the three-phase motor **108** during a protection phase. Identification using a relationship of the type shown in FIG. **8** is described below in more detail.

FIG. **9** is a block diagram of an example fault detection circuit **900** to detect a winding fault in a wye-connected three-phase motor. FIG. **10** is a block diagram of an example winding fault detection circuit **1000** to detect an winding fault in a delta-connected three-phase motor. Both of the example fault detection circuits **900**, **1000** of FIGS. **9** and **10** include a positive sequence voltage magnitude calculator **902**, a positive sequence current magnitude calculator **904**, a negative sequence voltage calculator **906**, an interpolator **908**, a fault detector **910**, a data acquisition controller **912**, and a learner **914**.

The example positive sequence voltage magnitude calculator **902** and the example negative sequence voltage calculator **906** receive an alpha voltage signal **916a** and a beta voltage signal **916b**, which are generated by a Clarke transformer **918** in FIG. **9**. In the example of FIG. **9**, the Clarke transformer **918** receives three phase voltages **920a**, **920b**, **920c** corresponding to the phase voltages of the motor (e.g., the voltages **306a-306c** of FIG. **3**), and converts the phase voltages **920a-920c** to the alpha voltage signal **916a** and the beta voltage signal **916b** using the Clarke transform (also referred to as the alpha-beta transform). The example fault detection circuit **1000** of FIG. **10** also includes a Clarke transformer **1002**, which receives two of the phase voltages **920a**, **920b**, **920c** (e.g., **920a** and **920b**, **920b** and **920c**, or **920a** and **920c**) instead of the three phase voltages **920a**, **920b**, **920c** received by the Clarke transformer **918** of FIG. **9**. FIGS. **12** and **22** described below illustrate examples of the alpha voltage signal **916a** and a beta voltage signal **916b** generated by the Clarke transformers **918**, **1002** of FIGS. **9** and/or **10**.

In some examples, the fault detection circuits **900**, **1000** include a PWM converter **968** that converts PWM signals to the phase voltages **920a-920c**. For example, the PWM converter **968** may receive the PWM signals **120a-120c** of FIGS. **1** and/or **2** and generate the phase voltages **920a-920c** from the PWM signals **120a-120c** (e.g., based on a voltage supply to the fault detection circuit **900** and based on the widths of the pulses as a fraction of a pulse period). In some other examples, the Clarke transformer **918** obtains the phase voltages **920a-920c** by sampling the three-phase power signals **106a-106c** (or two of the three-phase power signals **106a-106c** for the Clarke transformer **1004**) as shown in FIG. **3**.

Similarly, the example positive sequence current magnitude calculator **904** of FIG. **9** receives an alpha current signal **926a** and a beta current signal **926b** generated by a Clarke transformer **928**. The Clarke transformer **928** receives at least two phase currents **930a**, **930b** because, in the wye-connected motor, the third phase current **930c** can be calculated from the two phase currents **930a**, **930b**. The

example phase currents **930a**, **930b** may be, for example, two of the currents **124a-124c** of FIGS. **1** and/or **2**, and/or two of the currents **308a-308c** of FIG. **3**. However, in some other examples, the Clarke transformer **928** receives all three of the phase currents. The Clarke transformer **928** converts the two phase currents **930a**, **930b** to the alpha current signal **926a** and the beta current signal **926b** by determining the third phase current (e.g., by calculating a third current that balances the two phase currents **930a**, **930b** causing the sum of the three currents to be 0) and then using the Clarke transform.

Like the fault detection circuit **900**, the example fault detection circuit **1000** of FIG. **10** includes a Clarke transformer **1004**, which receives all three phase currents **930a**, **930b**, **930c** instead of the two phase currents **930a**, **930b** received by the Clarke transformer **928** of FIG. **9**. The example Clarke transformer **1004** converts the phase currents **930a**, **930b**, **930c** to the alpha current signal **926a** and the beta current signal **926b**. FIG. **17** described below illustrates examples of the alpha current signal **926a** and the beta current signal **926b**.

Other than the difference in the number of phase voltage inputs to the Clarke transformers **918**, **1002** and the difference in the number of phase current inputs to the Clarke transformers **928**, **1004** of FIGS. **9** and **10**, the example fault detection circuits **900**, **1000** are identical. Any modifications that can be made to one of the fault detection circuits **900**, **1000** are also applicable to the other. The remainder of the fault detection circuits **900**, **1000** of FIGS. **9** and **10** are described below with reference to FIG. **9**, and use the same reference indicators except where noted above.

The example positive sequence voltage magnitude calculator **902** receives the alpha voltage signal **916a** and the beta voltage signal **916b** generated by the Clarke transformer **918**, and calculates a positive sequence voltage magnitude value **932** for the three-phase motor under protection by the fault detection circuit **900** (e.g., the three-phase motor **108** of FIGS. **1-3**). The example positive sequence voltage magnitude calculator **902** is described in more detail below with reference to FIGS. **11-15**.

The example positive sequence voltage magnitude calculator **902** generates the positive sequence voltage magnitude value **932** during the training phase of the fault detection circuit **900** to provide baseline values for determining the characteristics of the motor with respect to negative sequence voltages. The example positive sequence voltage magnitude calculator **902** also generates the positive sequence voltage magnitude value **932** during the protection phase to determine an expected negative sequence voltage.

The example positive sequence current magnitude calculator **904** receives the alpha current signal **926a** and the beta current signal **926b**, and calculates a positive sequence current magnitude value **934** for the three-phase motor. The example positive sequence current magnitude calculator **904** is described in more detail below with reference to FIGS. **16-20**. The example positive sequence current magnitude calculator **904** generates the positive sequence current magnitude value **934** during the training phase of the fault detection circuit **900** to provide baseline values for determining the characteristics of the motor with respect to negative sequence voltages. The example positive sequence current magnitude calculator **904** also generates the positive sequence current magnitude value **934** during the protection phase to determine an expected negative sequence voltage.

The example negative sequence voltage calculator **906** receives the alpha voltage signal **916a** and the beta voltage signal **916b** generated by the Clarke transformer **918**, and

calculates a negative sequence voltage value (e.g., a direct negative sequence voltage value **936a** and a quadrature negative sequence voltage value **936b**) for the three-phase motor. The example negative sequence voltage calculator **906** is described in more detail below with reference to FIGS. **21-25**. The example negative sequence voltage calculator **906** generates the negative sequence voltage values **936a**, **936b** during the training phase of the fault detection circuit **900** to provide baseline values for determining the characteristics of the motor. The example negative sequence voltage calculator **906** also generates the negative sequence voltage values **936a**, **936b** during the protection phase for comparison with an expected negative sequence voltage.

The example fault detection circuit **900** operates in two phases: 1) a training phase, in which the learner **914** measures and stores the characteristics of the three-phase motor; and 2) a protection phase, in which the interpolator **908** uses the stored characteristics to determine the expected direct negative sequence voltage signal **938a** and/or the expected quadrature negative sequence voltage signal **938b** based on received values for the positive sequence voltage magnitude value **932** and the positive sequence current magnitude value **934**. During a protection phase of the fault detection circuit **900**, the example interpolator **908** calculates an expected negative sequence voltage value (e.g., an expected direct negative sequence voltage signal **938a** and/or an expected quadrature negative sequence voltage signal **938b**) based on the positive sequence voltage magnitude value **932**, the positive sequence current magnitude value **934**, and characteristics of the three-phase motor measured during the training phase.

The example interpolator **908** of FIGS. **9** and **10** may determine the expected direct negative sequence voltage signal **938a** and/or the expected quadrature negative sequence voltage signal **938b** using an interpolation equation method, a mesh method, and/or any other suitable interpolation method.

In the interpolation equation method, the example learner **914** fits a set of training data to an interpolation equation, such as the following example quadratic polynomial of Equation 1:

$$\tilde{v}_{ns} = a_0 + a_1 v_p + a_2 i_p + a_3 v_p^2 + a_4 i_p^2 + a_5 v_p i_p + a_6 v_p^2 i_p + a_7 i_p^2 v_p + a_8 v_p^2 i_p^2 \quad \text{Equation 1}$$

In the example Equation 1, v_p is the positive sequence voltage magnitude value **932** obtained from the positive sequence voltage magnitude calculator **902**, i_p is the positive sequence current magnitude value **934** obtained from the positive sequence current magnitude calculator **904**. The learner **914** calculates the coefficients a_0 - a_8 during a training phase to most closely approximate the characteristics of the three-phase motor based on a set of measured combinations of the positive sequence voltage magnitude value **932**, the positive sequence current magnitude value **934**, and the negative sequence voltage value(s) **936a**, **936b**. During the protection phase after the training phase, the interpolator **908** inputs a current operating point into the interpolation equation determined by the learner **914** to determine the expected negative sequence voltage value(s) **938a**, **938b**. The example learner **914** may incrementally update the coefficients a_0 - a_8 during operation of the fault detection circuit **900**.

Additionally or alternatively, the example learner **914** may use a recursive method to calculate the coefficients a_0 - a_8 . For example, the learner **914** may update the coefficients a_0 - a_8 each time a data point is collected. The recursive method reduces or avoids the need to store a table of data

11

points, but the learner **914** is unable to determine the boundaries of the operating space being explored.

In the mesh method, the example interpolator **908** determines a plane or other function based on stored set of points measured during the training phase. The example interpolator **908** determines the nearest neighboring points (e.g., 3 points) to the current operating point (e.g., combination of positive sequence voltage magnitude value **932** and positive sequence current magnitude value **934**) measured during the protection phase to create the plane, and then locates the current operating point within the calculated plane to determine the expected negative sequence voltage value(s) **938a**, **938b**.

The interpolation equation method has the advantages (over the mesh method) that the interpolation equation method may be used for any combination of positive sequence voltage magnitude value **932** and positive sequence current magnitude value **934**. Additionally, the interpolation equation method is efficient to determine the coefficients a_0 - a_8 , and storage requirements are reduced compared to the mesh method. However, the interpolation equation method does not necessarily retain information to enable the interpolator **908** to determine whether a current operating point is close to an operating point observed during the training phase.

The example mesh method has the advantages (over the interpolation equation method) of having a lower error between the expected negative sequence voltage value(s) **938a**, **938b** and the actual negative sequence voltage value(s) during normal operation of the three-phase motor. The mesh method also enables the interpolator **908** to efficiently determine the expected negative sequence voltage value(s) **938a**, **938b**. Additionally, because the training data is stored, the interpolator **908** is able to determine whether the current operating point is in an “unexplored” region that was not substantially evaluated during the training phase. However, the mesh method has a higher data storage requirement to implement than the interpolation equation method. Overall, the example mesh method disclosed herein provides higher detection sensitivities to winding faults than the interpolation equation method.

The following example discusses the mesh method in more detail. During the training phase, the example learner **914** receives combinations of the positive sequence voltage magnitude value **932**, the positive sequence current magnitude value **934**, the direct negative sequence voltage signal **936a** and/or the quadrature negative sequence voltage signal **936b**. The learner **914** constructs one or more baseline tables **940** in a storage device **942**. The baseline tables **940** function as lookup tables that map combinations of positive sequence voltage magnitude values **932** and positive sequence current magnitude values **934** measured during the training phase to corresponding values of the direct negative sequence voltage signal **936a** and/or the quadrature negative sequence voltage signal **936b** (or an amplitude calculated from the direct negative sequence voltage signal **936a** and the quadrature negative sequence voltage signal **936b**).

In the examples of FIGS. **9** and **10**, the learner **914** collects a set of combinations of positive sequence voltage magnitude values **932** and positive sequence current magnitude values **934**, and the corresponding values of the direct negative sequence voltage signal **936a** and/or the quadrature negative sequence voltage signal **936b**, where the learner **914** stores a newly measured combination of a positive sequence voltage magnitude value **932** and a positive sequence current magnitude value **934** when the measured combination has at least a threshold distance (e.g., Euclidean

12

distance) from all other combinations of positive sequence voltage magnitude values **932** and positive sequence current magnitude values **934**. In some examples, the learner **914** collects the combinations of positive sequence voltage magnitude values **932**, positive sequence current magnitude values **934**, when the positive sequence voltage magnitude values **932**, the positive sequence current magnitude values **934**, have less than threshold variations over a time duration (e.g., when the motor is in a steady state).

When a sufficient number of combinations of positive sequence voltage magnitude values **932** and positive sequence current magnitude values **934**, and the corresponding values of the direct negative sequence voltage signal **936a** and/or the quadrature negative sequence voltage signal **936b**, have been collected and stored in the baseline table(s) **940**, the example learner **914** stops collecting the combinations of the positive sequence voltage magnitude values **932** and the positive sequence current magnitude values **934**.

During the protection phase, the example interpolator **908** receives the positive sequence voltage magnitude values **932** and the positive sequence current magnitude values **934**. The interpolator **908** uses the baseline table(s) **940** and the received positive sequence voltage magnitude values **932** and the received positive sequence current magnitude values **934** to determine the expected direct negative sequence voltage signal **938a** and the expected quadrature negative sequence voltage signal **938b**.

To determine the expected direct negative sequence voltage signal **938a** and the expected quadrature negative sequence voltage signal **938b**, the example interpolator **908** selects a number of the stored points in the baseline table(s) **940** that are nearest to the current operating point, as defined by the positive sequence voltage magnitude value **932** and the positive sequence current magnitude value **934** (e.g., the nearest neighbors to the current operating point). The example interpolator **908** determines distances between the current operating point and the stored points in the baseline table(s) **940** using, for example, the Euclidean distance. In the examples of FIGS. **9** and **10**, the interpolator **908** determines the 4 nearest neighbors in the baseline table(s) **916**.

If the nearest neighbor is more than a threshold distance away from the current operating point, the interpolator **908** is inactivated and does not detect winding faults in the motor.

When the nearest neighbor is less than the threshold distance from the current operating point, the interpolator **908** selects the 3 nearest neighbors and checks the collinearity of the selected nearest neighbors using Equations 2-6 below:

$$\Delta x_2 = x_2 - x_1 \quad \text{Equation 2}$$

$$\Delta y_2 = y_2 - y_1 \quad \text{Equation 3}$$

$$\Delta x_3 = x_3 - x_1 \quad \text{Equation 4}$$

$$\Delta y_3 = y_3 - y_1 \quad \text{Equation 5}$$

$$d = \Delta x_2 \Delta y_3 - \Delta x_3 \Delta y_2 \quad \text{Equation 6}$$

In Equations 2-6 above and this example in general, the x variable refers to the positive sequence voltage magnitude value **932** (or the positive sequence current magnitude value **934**), and the y variable refers to the positive sequence current magnitude value **934** (or the positive sequence voltage magnitude value **932**). The ordered pair (x_1, y_1) refers to the nearest point to the operating point (e.g., by Euclidean distance), (x_2, y_2) refers to the second nearest

point to the operating point (e.g., by Euclidean distance), and (x_3, y_3) refers to the third nearest point to the operating point (e.g., by Euclidean distance). The co-linearity is determined by comparing d in Equation 6 to a threshold.

If the interpolator **908** determines that the selected nearest neighbors are too close being co-linear (e.g., a third one of the three selected points is less than a threshold distance from a line between the other two of the points), the interpolator **908** selects the second, third, and fourth nearest neighbor, and repeats the calculations of Equations 2-6 using the second, third, and fourth nearest neighbor instead of the first, second, and third nearest neighbors. When the interpolator **908** determines that one of the selected groups of 3 neighbors is acceptable, the interpolator **908** fits a plane to the points of the selected group using Equations 16-10 below:

$$\Delta z_2 = z_2 - z_1 \quad \text{Equation 7}$$

$$\Delta z_3 = z_3 - z_1 \quad \text{Equation 8}$$

$$G_x = \frac{\Delta z_2 \Delta y_3 - \Delta z_3 \Delta y_2}{\Delta x_2 \Delta y_3 - \Delta x_3 \Delta y_2} \quad \text{Equation 9}$$

$$G_y = \frac{\Delta z_3 \Delta x_2 - \Delta z_2 \Delta x_3}{\Delta x_2 \Delta y_3 - \Delta x_3 \Delta y_2} \quad \text{Equation 10}$$

In Equations 7-10 above, the z variable refers to the direct negative sequence voltage signal **936a** or the quadrature negative sequence voltage signal **936b**, z_1 refers to the negative sequence voltage (e.g., direct or quadrature) of the nearest neighbor (e.g., corresponding to (x_1, y_1)), z_2 refers to the negative sequence voltage of the second nearest neighbor (e.g., corresponding to (x_2, y_2)), and z_3 refers to the negative sequence voltage of the third nearest neighbor (e.g., corresponding to (x_3, y_3)). In some other examples, the z variable refers to the amplitude of the phasor form of the negative sequence voltage, which is determined using both the direct negative sequence voltage signal **936a** and the quadrature negative sequence voltage signal **936b**. In the example of FIGS. 9 and 10, the interpolator **908** performs Equations 7-10 for each of the direct negative sequence voltage signal **936a** and the quadrature negative sequence voltage signal **936b**.

After calculating the coefficients G_x and G_y , the example interpolator **908** calculates the expected negative sequence voltage, which may be the expected direct negative sequence voltage signal **938a**, the expected quadrature negative sequence voltage signal **938b**, and/or an amplitude from which the direct and quadrature components can be computed, using Equation 11 below:

$$z_e = z_1 + G_x(x_0 - x_1) + G_y(y_0 - y_1) \quad \text{Equation 11}$$

In Equation 11, (x_0, y_0) is the current operating point, and z_e is the expected negative sequence voltage. If both groups of three nearest neighbors selected by the interpolator **908** are too co-linear, the interpolator **908** selects the nearest neighbor point (x_1, y_1) if the nearest neighbor operating point is within a threshold distance (e.g., Euclidean distance) to the operating point. Otherwise, fault detection by the fault detection circuit **900** is disabled until the operating point (x_0, y_0) changes.

The example fault detection circuit **900** further includes subtractors **944a**, **944b**. The example subtractor **944a** subtracts the expected direct negative sequence voltage signal **938a** from the direct negative sequence voltage signal **936a** output by the negative sequence voltage calculator **906** (or

the subtracts the direct negative sequence voltage signal **936a** from the expected direct negative sequence voltage signal **938a**) to generate a direct negative sequence voltage difference value **946a**. Similarly, the example subtractor **944b** subtracts the expected quadrature negative sequence voltage signal **938b** from a filtered quadrature negative sequence voltage signal **936b** output by the negative sequence voltage calculator **906** (or the subtracts the quadrature negative sequence voltage signal **936b** from the expected quadrature negative sequence voltage signal **938b**) to generate a quadrature negative sequence voltage difference value **946b**.

The example fault detection circuit **900** includes an amplitude calculator **948** that determines the amplitude of the direct negative sequence voltage difference value **946a** and the quadrature negative sequence voltage difference value **946b**. For example, the amplitude calculator **948** may convert the difference values **946a** and **946b** to a phasor (e.g., an amplitude and phase angle notation), and extracts the amplitude portion of the phasor to output a negative sequence voltage difference value **950**.

The example fault detection circuit **900** also includes a high pass filter **952** to detect whether the positive sequence voltage magnitude value **932** and/or the positive sequence current magnitude value **934** are changing. For example, the high pass filter **952** is configured with a cutoff frequency, below which changes to the positive sequence voltage magnitude value **932** and/or the positive sequence current magnitude value **934** do not affect fault detection. The example high pass filter **952** outputs a high pass filtered positive sequence voltage magnitude value **954** and a high pass filtered positive sequence current magnitude value **956** to the fault detector **910**. As discussed below, the fault detector **910** compares the high pass filtered positive sequence voltage magnitude value **954** and/or the high pass filtered positive sequence current magnitude value **956** to threshold(s) to determine whether to disable fault detection.

The example fault detector **910** detects whether a winding fault exists in the three-phase motor when the negative sequence voltage difference value **950** (e.g., a difference between the expected negative sequence voltage values **938a**, **938b** and the measured negative sequence voltage values **936a**, **936b**) satisfies a threshold. In the example of FIG. 9, the fault detector **910** only detects faults when the motor is operating in a steady state (e.g., a substantially steady load and speed). The example fault detector **910** of FIGS. 9 and 10 implements a state machine that monitors whether the three-phase motor is in a transient state (e.g., the load and/or the speed of the motor are changing) or a steady state (e.g., the load and/or the speed of the motor are constant). The example fault detector **910** determines whether the motor is in a transient state by comparing the high pass filtered positive sequence voltage magnitude value **954** and/or the high pass filtered positive sequence current magnitude value **956** to threshold value(s). When the high pass filtered positive sequence voltage magnitude value **954** and the high pass filtered positive sequence current magnitude value **956** are less than the threshold value(s), the example fault detector **910** determines that the three-phase motor is in a steady state.

When the fault detector **910** determines that the three-phase motor is in a steady state, and the negative sequence voltage difference value **950** is more than a threshold, the example fault detector **910** determines that a winding fault has occurred and outputs a fault detection signal **958**. The fault detector **910** does not stop asserting the fault detection

signal **958** until reset by, for example, an operator of the motor and/or via the motor controller **110** of FIG. **1**.

The example positive sequence voltage magnitude calculator **902**, the example positive sequence current magnitude calculator **904**, and the example negative sequence voltage calculator **906** of FIGS. **9** and **10** are controlled by the data acquisition controller **912** using control signals, including a phase angle signal **960**, a window phase angle signal **962**, a reset signal **964**, and a latch signal **966** as described below. The example data acquisition controller **912** and generation of the control signals **960-966** are described in more detail below with reference to FIG. **26**.

FIG. **11** illustrates an example positive sequence voltage magnitude calculator **902** that may implement the example positive sequence voltage magnitude calculator **902** of FIGS. **9** and **10**. FIGS. **12-15** illustrate example signals that are generated within the example positive sequence voltage magnitude calculator **902** of FIG. **11** while calculating the positive sequence voltage magnitude value **932** for a three-phase motor.

The example positive sequence voltage magnitude calculator **902** receives the alpha voltage signal **916a** and the beta voltage signal **916b** generated by the Clarke transformer **918**, and calculates a positive sequence voltage magnitude value **932** for the three-phase motor under protection by the fault detection circuit **900** (e.g., the three-phase motor **108** of FIGS. **1-3**). The example positive sequence voltage magnitude calculator **902** includes a Park transformer **1102**, a windower **1104**, an integrator **1106**, a positive sequence voltage magnitude buffer **1108**, and an amplitude calculator **1110**.

The example Park transformer **1102** performs a Park transform on the alpha voltage signal **916a** and the beta voltage signal **916b** by converting the alpha voltage signal **916a** and the beta voltage signal **916b** from a balanced two-phase orthogonal stationary system (e.g., generated using the Clarke transformation) into an orthogonal rotating reference frame determined based on the phase angle signal **960**. The example Park transformer **1102** allows the alpha voltage signal **916a** and the beta voltage signal **916b** to be observed at the positive excitation frequencies. The Park transformer **1102** outputs a direct positive sequence voltage signal **1112a** and a quadrature positive sequence voltage signal **1112b**. FIG. **12** illustrates examples of the alpha voltage signal **916a** and the beta voltage signal **916b** input to the positive sequence voltage magnitude calculator **902** from the Clarke transformers **918**, **1002** of FIG. **9** or **10**. FIG. **13** illustrates examples of the direct positive sequence voltage magnitude signal **1112a** and the quadrature positive sequence voltage magnitude signal **1112b** that may be generated by the Park transformer **1102** using the signals of FIG. **12**.

The example windower **1104** performs windowing on the direct positive sequence voltage magnitude signal **1112a** and the quadrature positive sequence voltage magnitude signal **1112b**. For example, the windower **1104** may apply a window function to the direct positive sequence voltage signal **1112a** and the quadrature positive sequence voltage signal **1112b** to generate a windowed direct positive sequence voltage signal **1114a** and a windowed quadrature positive sequence voltage signal **1114b**. In the example of FIG. **11**, the windower **1104** multiplies the direct positive sequence voltage signal **1112a** and the quadrature positive sequence voltage signal **1112b** by a Kaiser window based on the phase window angle signal **962** to eliminate high frequencies which can be caused by discontinuous boundary conditions.

The example integrator **1106** of FIG. **11** integrates the example windowed direct positive sequence voltage signal **1114a** and the windowed quadrature positive sequence voltage signal **1114b** to generate an integrated direct positive sequence voltage signal **1116a** and an integrated quadrature positive sequence voltage signal **1116b**. The example integrator **1106** is reset in response to the reset signal **964** from the data acquisition controller **912** of FIGS. **9** and/or **10**. FIG. **14** illustrates examples of the integrated direct positive sequence voltage signal **1116a** and the integrated quadrature positive sequence voltage signal **1116b** that may be generated by the integrator **1106** using windowed versions of the signals of FIG. **13**.

The example positive sequence voltage buffer **1108** of FIG. **11** receives the integrated direct positive sequence voltage signal **1116a** and the integrated quadrature positive sequence voltage signal **1116b**, and generates a direct positive sequence voltage signal **1118a** and a quadrature positive sequence voltage signal **1118b**. Examples of the direct positive sequence voltage signal **1118a** and the quadrature positive sequence voltage signal **1118b** are illustrated in FIG. **15**.

In response to the latch signal **966** of FIGS. **9** and/or **10**, the example positive sequence voltage buffer **1108** outputs the direct positive sequence voltage signal **1118a** and the quadrature positive sequence voltage signal **1118b** to the amplitude calculator **1110**, which calculates the amplitude of the positive sequence voltage magnitude value **932** using the direct positive sequence voltage signal **1118a** and the quadrature positive sequence voltage signal **1118b**. For example, the amplitude calculator **1110** may convert the direct positive sequence voltage signal **1118a** and the quadrature positive sequence voltage signal **1118b** to a phasor notation, which includes the amplitude and phase angle, and then output the amplitude portion as the positive sequence voltage magnitude value **932**.

FIG. **16** illustrates an example positive sequence current magnitude calculator **904** that may implement the example positive sequence current magnitude calculator **904** of FIGS. **9** and **10**. FIGS. **17-20** illustrate example signals that are generated within the example positive sequence current magnitude calculator **904** of FIG. **16** while calculating a positive sequence voltage magnitude value for a three-phase motor.

The example positive sequence current magnitude calculator **904** calculates a positive sequence current magnitude value **934** for the three-phase motor. The example positive sequence current magnitude calculator **904** includes a Park transformer **1602**, a windower **1604**, an integrator **1606**, a positive sequence current magnitude buffer **1608**, and an amplitude calculator **1610**. The example Park transformer **1602**, the example windower **1604**, the example integrator **1606**, the example positive sequence current magnitude buffer **1608**, and the example amplitude calculator **1610** function in the same ways as the respective ones of the Park transformer **1102**, the windower **1104**, the integrator **1106**, the positive sequence voltage buffer **1108**, and the amplitude calculator **1110**, except that the Park transformer **1602**, the example windower **1604**, the example integrator **1606**, the example positive sequence current magnitude buffer **1608**, and the example amplitude calculator **1610** execute on current values (e.g., the alpha current signal **926a** and the beta current signal **926b**) instead of voltage values.

The example Park transformer **1602** receives the alpha current signal **926a** and the beta current signal **926b**, and generates a direct positive sequence current signal **1612a** and a quadrature positive sequence current signal **1612b**.

based on the phase angle signal **960** in a similar manner to the operation of the Park transformer **1102** described above. FIG. **17** illustrates examples of the alpha current signal **926a** and the beta current signal **926b** input to the positive sequence current magnitude calculator **904** from the Clarke transformers **928**, **1004** of FIG. **9** or **10**. FIG. **18** illustrates examples of the direct positive sequence current signal **1612a** and the quadrature positive sequence current signal **1612b** generated by the example Park transformer **1602**.

The example windower **1604** receives the direct positive sequence current signal **1612a** and the quadrature positive sequence current signal **1612b**, and generates a windowed direct positive sequence current signal **1614a** and a windowed quadrature positive sequence current signal **1614b** based on the window phase angle signal **962** in a similar manner to the operation of the windower **1104** described above.

The example integrator **1606** receives the windowed direct positive sequence current signal **1614a** and the windowed quadrature positive sequence current signal **1614b**, and generates an integrated direct positive sequence current signal **1616a** and an integrated quadrature positive sequence current signal **1616b** in a manner similar to the integrator **1106** described above. The example integrator **1606** is reset (e.g., to an initial value or sum) in response to the reset signal **964** from the data acquisition controller **912** of FIGS. **9** and/or **10**. FIG. **19** illustrates examples of the integrated direct positive sequence current signal **1616a** and the integrated quadrature positive sequence current signal **1616b** that may be generated by the integrator **1606** using windowed versions of the signals of FIG. **18**.

The example positive sequence current buffer **1608** receives the integrated direct positive sequence current signal **1616a** and the integrated quadrature positive sequence current signal **1616b**, and generates a direct positive sequence current signal **1618a** and a quadrature positive sequence current signal **1618b**. Examples of the direct positive sequence current signal **1618a** and the quadrature positive sequence current signal **1618b** are illustrated in FIG. **20**.

In response to the latch signal **966**, the example positive sequence current buffer **1608** outputs the direct positive sequence current signal **1618a** and the quadrature positive sequence current signal **1618b** to the amplitude calculator **1610**, which calculates the amplitude of the direct positive sequence current signal **1618a** and the quadrature positive sequence current signal **1618b**. For example, the amplitude calculator **1610** may convert the direct positive sequence current signal **1618a** and the quadrature positive sequence current signal **1618b** to a phasor notation, which includes the amplitude and phase angle, and then output the amplitude portion as the positive sequence current magnitude value **934** in a manner similar to the amplitude calculator **1110** described above.

FIG. **21** illustrates an example negative sequence voltage calculator **906** that may implement the example negative sequence voltage calculator **906** of FIGS. **9** and **10**. FIGS. **22-25** illustrate example signals that are generated within the example negative sequence voltage calculator **906** of FIGS. **9**, **10**, and/or **21** while calculating a negative sequence voltage value for a three-phase motor.

The example negative sequence voltage calculator **906** calculates measured negative sequence voltage values **936a**, **936b** for the three-phase motor. The example negative sequence voltage calculator **906** includes an inverse-Park

transformer **2102**, a windower **2104**, an integrator **2106**, a negative sequence voltage buffer **2108**, and a low-pass filter **2110**.

The example inverse-Park transformer **2102** receives the alpha voltage signal **916a** and the beta voltage signal **916b** and performs an inverse Park transformation to generate a direct negative sequence voltage signal **2112a** and a quadrature negative sequence voltage signal **2112b**. The inverse Park transformer **2102** obtains the voltage at the negative excitation frequency, in contrast with the positive excitation frequency obtained by the Park transformers **1102**, **1602**. The inverse Park transformer **2102** is controlled via the phase angle signal **960** from the data acquisition controller **912** of FIGS. **9** and/or **10**. FIG. **22** illustrates examples of the alpha voltage signal **916a** and the beta voltage signal **916b** input to the negative sequence voltage calculator **906** from the Clarke transformers **918**, **1002** of FIG. **9** or **10**. FIG. **23** illustrates examples of the direct negative sequence voltage signal **2112a** and the quadrature negative sequence voltage signal **2112b** based on the alpha voltage signal and the beta voltage signal of FIG. **22**.

The example windower **2104** receives the direct negative sequence voltage signal **2112a** and the quadrature negative sequence voltage signal **2112b**, and applies a window function to generate a windowed direct negative sequence voltage signal **2114a** and a windowed quadrature negative sequence voltage signal **2114b**. The example windower **2104** may apply a similar, identical, or different window function as the windowers **1104**, **1604**. For example, the windower **2104** applies a Kaiser window based on the window phase angle signal **962** to the direct negative sequence voltage signal **2112a** and the quadrature negative sequence voltage signal **2112b**.

The example integrator **2106** receives the windowed direct negative sequence voltage signal **2114a** and the windowed quadrature negative sequence voltage signal **2114b**, and integrates the windowed direct negative sequence voltage signal **2114a** and the windowed quadrature negative sequence voltage signal **2114b** to generate an integrated direct negative sequence voltage signal **2116a** and an integrated quadrature negative sequence voltage signal **2116b**. The integrator **2106** removes AC component(s) present in the windowed direct negative sequence voltage signal **2114a** and the windowed quadrature negative sequence voltage signal **2114b** to produce the negative sequence voltage. The example integrator **2106** is reset in response to the reset signal **964** from the data acquisition controller **912** of FIGS. **9** and/or **10**. FIG. **24** illustrates examples of the integrated direct negative sequence voltage signal **2116a** and the integrated quadrature negative sequence voltage signal **2116b** based on windowed version of the signals of FIG. **23**.

The example negative sequence voltage buffer **2108** of FIG. **21** receives the integrated direct negative sequence voltage signal **2116a** and the integrated quadrature negative sequence voltage signal **2116b**, and generates a direct negative sequence voltage signal **2118a** and a quadrature negative sequence voltage signal **2118b**. The example negative sequence voltage buffer **2108** outputs the direct negative sequence voltage signal **2118a** and a quadrature negative sequence voltage signal **2118b** to the low pass filter **2110** in response to the latch signal **966**. Examples of the direct negative sequence voltage signal **2118a** and the quadrature negative sequence voltage signal **2118b** are illustrated in FIG. **25**.

The example low pass filter **2110** of FIG. **21** filters the direct negative sequence voltage signal **2118a** and the quadrature negative sequence voltage signal **2118b** to

attenuate transients in the direct negative sequence voltage signal **2118a** and/or the quadrature negative sequence voltage signal **2118b**, and/or to remove cycle-to-cycle variations in the direct negative sequence voltage signal **2118a** and/or the quadrature negative sequence voltage signal **2118b**. The example low pass filter **2110** outputs the filtered negative sequence voltage signals as the direct negative sequence voltage signal **936a** and the quadrature negative sequence voltage signal **936b**. As explained in more detail below, relatively stable (e.g., steady state) negative sequence voltage signals are used to detect winding faults instead of transient negative sequence voltage signals.

FIG. **26** illustrates an example data acquisition controller **2600** that may implement the example data acquisition controller **912** of FIGS. **9** and **10**. The example data acquisition controller of FIG. **26** receives a phase voltage signal (e.g., the phase voltage signal **920a** of FIGS. **9** and/or **10**) and outputs the phase angle signal **960**, the phase window angle signal **962**, the reset signal **964**, and the latch signal **966** of FIGS. **9** and **10** to control the positive sequence voltage calculator **902**, the positive sequence current calculator **904**, and the negative sequence voltage calculator **906**.

The example data acquisition controller **2600** of FIG. **26** includes a zero-crossing detector **2602**, a sample counter **2604**, an angular change calculator **2606**, a sampling clock **2608**, a phase angle calculator **2610**, a window angle calculator **2612**, and a reset trigger **2614**.

The example zero crossing detector **2602** receives the phase voltage signal **920a** and identifies positive zero crossings in the phase voltage signal **920a** (e.g., zero crossings in which the phase voltage signal **920a** is changing from a negative voltage to a positive voltage with respect to the zero reference). The example zero crossing detector **2602** outputs a zero crossing signal **2616** in response to identifying a positive zero crossing (e.g., each time the zero crossing detector **2602** detects the positive zero crossing event).

The example sample counter **2604** calculates a number of cycles of the sampling clock **2608** between zero crossings in the phase voltage signal **920a**. The sample counter **2604** outputs a zero crossing period (e.g., in samples) of the phase voltage signal **920a**. To calculate the zero crossing period, the example sample counter **2604** resets a sampling clock counter and begins counting cycles of a sampling clock signal **2618** when a first zero crossing signal **2616** is received. When a second zero crossing signal **2616** is received, the example sample counter **2604** outputs the counted number of sampling clock cycles **2620** counted by the sampling clock counter. The duration of the sampling cycle is based on the clock signal **2618** received from the sampling clock **2608**. In the example of FIG. **26**, the frequency of the clock signal **2618** is substantially higher than the frequency of the phase voltage signal **920a** (e.g., higher than the Nyquist frequency for the phase voltage signal **920a**). For example, the clock signal **2618** may have a 10 kHz frequency when the phase voltage signal **920a** has a frequency between 1 Hz and 500 Hz (e.g., 60 Hz).

The example angular change calculator **2606** receives the counted number of sampling clock cycles **2620** and calculates a reciprocal of the counted number of sampling clock cycles **2620**, which is an angular rate of change in the phase of the phase voltage signal **920a** per sample. The angular change calculator **2606** outputs the calculated angular rate of change **2622**.

In some examples, the angular change calculator **2606** repeatedly calculates the angular rate of change **2622**, in response to receiving the counted number of sampling clock cycles **2620**. The angular change calculator **2606** may low

pass filters (e.g., averages) the angular rate of change **2622** prior to outputting the angular rate of change **2622**. Additionally or alternatively, the example angular change calculator **2606** converts the angular rate of change **2622** to degrees.

The example phase angle calculator **2610**, the example window angle calculator **2612**, and the example reset trigger **2614** may implement one or more state machines **2624**. An example of such a state machine **2624** is described below with reference to the flowchart of FIG. **36**. The example state machine **2624** changes between a “Wait” state and an “Acquisition” state. The transition from the “Wait” state to the “Acquisition” state in the state machine **2624** occurs in response to the zero crossing signal **2616**, at which time the phase angle calculator **2610**, the example window angle calculator **2612**, and the example reset trigger **2614** perform actions as described below. When sample collection has completed in the “Acquisition” state, the state machine **2624** transitions from the “Acquisition” state to the “Wait” state.

The example phase angle calculator **2610** of FIG. **26** receives the zero crossing signal **2616**, the sampling clock signal **2618**, and the angular rate of change **2622** (e.g., in degrees) as inputs. The phase angle calculator **2610** calculates and outputs the phase angle signal **960**. The phase angle signal **960** has a range of 0° to 360° , or an equivalent such as 0 to 2π radians, and changes in value from 0° to 360° over the duration of the phase period **2620**. When the phase angle calculator **2610** receives the zero crossing signal **2616**, the phase angle calculator **2610** resets the phase angle signal **960** to 0° and increments the phase angle signal **960** by the angular rate of change **2622** each time the sampling clock signal **2618** is received. Assuming a constant frequency of the phase voltage signal **920a**, the phase angle calculator **2610** outputs values of the phase angle signal **960** that approach 360° by the time the next zero crossing signal **2616** is received.

The example window angle calculator **2612** of FIG. **26** receives the zero crossing signal **2616**, the sampling clock signal **2618**, the phase period **2620**, and the number of electrical cycles **2622** as inputs. In the example of FIG. **26**, sample counter **2604** repeatedly calculates the counted number of sampling clock cycles **2620** and low pass filters (e.g., averages) the counted number of sampling clock cycles **2620** provided to the window angle calculator **2612**. The low pass filtering reduces quantization error in the counted number of sampling clock cycles **2620**.

The window angle calculator **2612** calculates and outputs the window phase angle signal **962**. Like the phase angle signal **960**, the window phase angle signal **962** has a range of 0° to 360° , or an equivalent such as 0 to 2π radians. However, in contrast to the phase angle signal **960**, the window phase angle signal **962** changes in value from 0° to 360° over the duration of the number of electrical cycles **2622** calculated by the sample counter **2604**.

When the window angle calculator **2612** receives a first zero crossing signal **2616** (e.g., while the state machine **2624** is in the “Wait” state), the window angle calculator **2612** resets the window phase angle signal **962** to 0° . The example window angle calculator **2612** calculates an increment value for the window phase angle **962** by calculating a target number of cycles. In the example of FIG. **26**, the window angle calculator **2612** calculates the target number of cycles by multiplying the angular rate of change **2622** and a target number of samples **2626**, and rounding the product up to a nearest power of 2. The target number of samples may be specified by a variable or otherwise calculated to determine a number of samples to be integrated to obtain accurate

measurements via the positive sequence voltage magnitude calculator **902**, the positive sequence current magnitude calculator **904**, and the negative sequence voltage calculator **906**.

During the “Acquisition” state, the example window angle calculator **2612** increments the window phase angle signal **962** each time the sampling clock signal **2618** is received. In the example of FIG. **26**, the window angle calculator **2612** calculates the increment value by dividing the angular rate of change **2622** by the calculated target number of cycles. For example, if the angular rate of change **2622** is AO and the calculated target number of electrical cycles is N, the window angle calculator **2612** increments the window phase angle signal **962** by $\Delta\theta/N$ each time the sampling clock signal **2618** is received.

In addition to incrementing the window phase angle signal **962**, the example window angle calculator **2612** decrements a sample counter in response to the sampling clock signal **2618**. The sample counter is set to the target number of samples when the state machine **2624** transitions from the “Wait” state to the “Acquisition” state, and counts down to 0. When the sample counter reaches 0, the example state machine **2624** transitions back to the “Wait” state.

The example reset trigger **2614** of FIG. **26** receives the zero crossing signal **2616** as an input. When the zero crossing signal **2616** is received while the state machine **2624** is in the “Wait” state (e.g., a pulse from the zero crossing detector **2602**), the reset trigger **2614** outputs the reset signal **964** (e.g., a pulse) and/or the latch signal **966** (e.g., a pulse).

The example data acquisition controller **912** controls the Park transformers **1102**, **1602** of FIGS. **11** and **16** and the inverse Park transformer **2102** of FIG. **21** using the phase angle signal **960**. The data acquisition controller **912** controls the windowers **1104**, **1604**, **2104** using the window phase angle signal **962**. The example data acquisition controller **912** controls the integrators **1106**, **1606**, **2106** using the reset signal **964**, and controls the buffer circuits **1108**, **1608**, **2108** using a latch signal **966**. The reset signal **964** may be, for example, a pulse that causes the integrators **1106**, **1606**, **2106** to reset the current sum to 0, from which the integrator **1106**, **1606**, **2106** may resume summing.

The latch signal **966** causes the buffers **1108**, **1608**, **2108** to output the respective values stored in the buffers **1108**, **1608**, **2108** (e.g., from a previous integration) for calculation of the positive sequence voltage magnitude value **932** (e.g., via the amplitude calculator **1110**), the positive sequence current magnitude value **934** (e.g., via the amplitude calculator **1610**), the expected direct negative sequence voltage signal **938a** (e.g., via the interpolator **908**), the expected quadrature negative sequence voltage signal **938b** (e.g., via the interpolator **908**), the direct negative sequence voltage signal **936a** (e.g., via the low pass filter **2110**), and/or the quadrature negative sequence voltage signal **936b** (e.g., via the low pass filter **2110**). The result of the latch signal **966** is to provide the negative sequence voltage difference value **950**, the high pass filtered positive sequence voltage magnitude value **954**, and the high pass filtered positive sequence current magnitude value **956** to the fault detector **910** for detection of a winding fault in the three-phase motor.

FIG. **27** is an example state machine **2700** representative of logic that may be implemented by the learner **914** of FIGS. **9** and **10** during a training phase to store a set of training negative sequence voltage values corresponding to combinations of training positive sequence voltage magnitude values and training positive sequence current magnitude values. For example, when in the training phase, the

example learner **914** stores the combinations of negative sequence voltage values, positive sequence voltage magnitude values, and positive sequence current magnitude values when a) a combination is at least a threshold distance from all other stored combinations and b) the combination to be stored is sufficiently stable (e.g., non-transient).

The example state machine **2700** includes an idle state **2702**, a transient state **2704**, and a stable state **2706**. The example learner **914** is in the idle state **2702** when the fault detection circuit **900**, **1000** are in protection mode.

In some examples, when the fault detection circuit **900**, **1000** is initialized (e.g., turned on, started up), the example learner **914** initializes in the transient state **2704**. In some other examples, the learner **914** initializes in the idle state **2702** and transitions **2708** to the transient state **2704** in response to a start learning flag. In the transient state **2704**, the example learner **914** monitors the high pass filtered positive sequence voltage magnitude value **954** and the high pass filtered positive sequence current magnitude value **956** and compares them to threshold(s) ϵ_{TH} . The example threshold(s) ϵ_{TH} may be, for example, a percentage change. In the example of FIG. **27**, the threshold(s) are set to be relatively low values to reflect a low threshold for identifying a transient state in the high pass filtered positive sequence voltage magnitude value **954** and the high pass filtered positive sequence current magnitude value **956**.

While either of the high pass filtered positive sequence voltage magnitude value **954** or the high pass filtered positive sequence current magnitude value **956** are greater than the respective threshold(s) ϵ_{TH} , or if the high pass filtered positive sequence voltage magnitude value **954** and the high pass filtered positive sequence current magnitude value **956** are both less than the respective threshold(s) ϵ_{TH} for less than a threshold time T_{TH} , the example learner **914** remains in the transient state **2704** via a self-transition **2710**.

On the other hand, when the high pass filtered positive sequence voltage magnitude value **954** and the high pass filtered positive sequence current magnitude value **956** are both less than the respective threshold(s) ϵ_{TH} for at least the threshold time T_{TH} , the example learner **914** transitions **2712** to the stable state **2706**.

As part of or in response to the transition **2712**, the example learner **914** compares the stored combinations of the positive sequence voltage magnitude value **932** and the positive sequence current magnitude value **934** to the current operating point (x_0, y_0) (e.g., a received positive sequence voltage magnitude value **932** and positive sequence current magnitude value **934** from which the high pass filtered positive sequence voltage magnitude value **954** and the high pass filtered positive sequence current magnitude value **956** are generated by the high pass filter **952**) to determine a nearest neighbor (x_1, y_1) to the current operating point. In other words, the learner **914** determines a stored combination that is closest to the current operating point (x_0, y_0) . When the nearest neighbor (x_1, y_1) is identified, the example learner **914** determines whether a distance d (e.g., the Euclidean distance) between the current operating point (x_0, y_0) and the nearest neighbor (x_1, y_1) to a threshold distance d_{TH} . If the current operating point (x_0, y_0) is less than the threshold distance d_{TH} from the nearest neighbor (x_1, y_1) , the example learner **914** directly enters the stable state **2706**.

On the other hand, if the current operating point (x_0, y_0) is more than the threshold distance d_{TH} from the nearest neighbor (x_1, y_1) , the example learner **914** compares a size s of the table (e.g., a number of stored combinations in the baseline table **940**) to a threshold table size s_{TH} . When the distance is more than the threshold distance d_{TH} , and the size

s of the baseline table **940** is less than threshold table size s_{TH} , the example learner **914** stores the current operating point (x_0, y_0) as a combination in the baseline table **940**, in association with the negative sequence voltage values of the current operating point (x_0, y_0) (e.g., from the negative sequence voltage calculator **906**).

The example learner **914** remains in the stable state **2706** while the high pass filtered positive sequence voltage magnitude value **954** and the high pass filtered positive sequence current magnitude value **956** are both less than the respective threshold(s) ϵ_{TH} via a self-transition **2714**. When either of the high pass filtered positive sequence voltage magnitude value **954** or the high pass filtered positive sequence current magnitude value **956** are greater than the respective threshold(s) ϵ_{TH} , the example learner **914** transitions **2716** from the stable state **2706** to the transient state **2704**.

When the table has at least a threshold number of combinations, the example learner **914** (or the interpolator **908** reading the table) sets a stop learning flag, which causes the learner **914** to transition **2718** from either the transient state **2704** or the stable state **2706** to the idle state **2702**.

FIG. **28** is a graph **2800** illustrating an example set of negative sequence voltage values **2802** corresponding to combinations of positive sequence voltage magnitude values **2804** and positive sequence current magnitude values **2806** that may be stored by the example learner **914** of FIGS. **9** and/or **10** while implementing the state machine **2700** of FIG. **27** during a training phase. The example combinations of negative sequence voltage values **2802**, positive sequence voltage magnitude values **2804**, and positive sequence current magnitude values **2806** are stored in the example baseline table(s) **940** in the storage device **942** of FIGS. **9** and/or **10**. The example points in the graph **2800** are example data points representing a combination of a negative sequence voltage value **2802**, measured at a corresponding combination of a positive sequence voltage magnitude value **2804** and a positive sequence current magnitude value **2806**. Because each motor is different and/or due to variations in construction of the fault detection circuits **900**, **1000**, the example graph **2800** and the points in the graph **2800** will be different for different implementations, which advantageously increases the sensitivity of the fault detection circuits to low level winding faults.

FIG. **29** is an example state machine **2900** representative of logic that may be implemented by the fault detector **910** of FIGS. **9** and/or **10** during a protection phase to detect a winding fault in a three-phase motor. As mentioned above, the example fault detector **910** receives the high pass filtered positive sequence voltage magnitude value **954**, the high pass filtered positive sequence current magnitude value **956**, and a negative sequence voltage difference value **950**. The example state machine **2900** of FIG. **29** includes a transition state **2902**, a stable state **2904**, and a fault state **2906**.

The example fault detector **910** is in the transition state **2902** when the high pass filtered positive sequence voltage magnitude value **954** and/or the high pass filtered positive sequence current magnitude value **956** indicate that the three-phase motor is transient (e.g., the speed of the motor is changing and/or the load on the motor is changing). In the example state machine **2900**, the fault detector **910** is initialized into the transition state **2902** to avoid an false fault detection upon initialization.

The example transient state **2902** is similar to the transient state **2704** of FIG. **27**, and the example stable state **2904** is similar to the example stable state **2706** of FIG. **27**. In particular, transitions between the transient state **2902** and

the stable state **2904** use a same or similar threshold ϵ_{TH} as in the example state machine **2700** of FIG. **27**.

While either of the high pass filtered positive sequence voltage magnitude value **954** or the high pass filtered positive sequence current magnitude value **956** are greater than the respective threshold(s) ϵ_{TH} , or if the high pass filtered positive sequence voltage magnitude value **954** and the high pass filtered positive sequence current magnitude value **956** are both less than the respective threshold(s) ϵ_{TH} for less than a threshold time T_{TH} , the example fault detector **910** remains in the transient state **2902** via a self-transition **2908**.

On the other hand, when the high pass filtered positive sequence voltage magnitude value **954** and the high pass filtered positive sequence current magnitude value **956** are both less than the respective threshold(s) ϵ_{TH} for at least the threshold time T_{TH} , the example learner **914** transitions **2910** to the stable state **2904**. In the stable state **2706**, the example fault detector **910** may detect that a fault has occurred based on comparing the negative sequence voltage difference value **950** to a threshold deviation dev_{TH} . If the example fault detector **910** determines that the negative sequence voltage difference value **950** is more than the threshold deviation dev_{TH} for at least a threshold number of consecutive samples of the negative sequence voltage difference value **950**, the example fault detector **910** transitions to the fault state **2906** via a fault detection transition **2912**.

In the fault state **2906**, the example fault detector **910** outputs the fault detection signal **958** (e.g., a fault flag), which may be received by an operator of the motor to inform the operator of the potential winding fault condition. The example fault detector **910** remains in the fault state **2906** via a self-transition **2914** until the fault detection signal **958** (e.g., the fault flag) is reset. For example, after investigating the fault detection signal **958**, the operator may determine that no fault exists and reset the fault detection signal **958**, which causes the fault detector **910** to return to the stable state **2904** via a reset transition **2916**.

If no fault is detected while the fault detector **910** is in the stable state **2904**, the example fault detector **910** remains in the stable state **2904** via a self-transition **2918** while the high pass filtered positive sequence voltage magnitude value **954** and the high pass filtered positive sequence current magnitude value **956** are both less than the respective threshold(s) ϵ_{TH} . On the other hand, if either of the high pass filtered positive sequence voltage magnitude value **954** and/or the high pass filtered positive sequence current magnitude value **956** satisfy the respective threshold(s) ϵ_{TH} , the example fault detector **910** transitions **2920** to the transient state **2902**.

FIG. **30** illustrates an example operating point space **3000** including a set of negative sequence voltage values **3002-3040**. The negative sequence voltage values **3002-3040** are located within the operating point space **3000** based on combinations of positive sequence voltage magnitude values and positive sequence current magnitude values that correspond to the negative sequence voltage values **3002-3040**. The example interpolator **908** of FIGS. **9** and/or **10** determines an expected direct negative sequence voltage signal **938a** and/or an expected quadrature negative sequence voltage signal **938b** from the negative sequence voltage values **3002-3040**. In some examples, the negative sequence voltage values **3002-3040** are amplitudes from which the direct and quadrature components can be calculated.

The example interpolator **908** of FIG. **9** identifies the location of a current operating point **3042** in the operating point space **3000** based on the positive sequence voltage magnitude value **932** (e.g., $|V_p|$) received from the positive

sequence voltage magnitude calculator **902** and the positive sequence current magnitude value **934** (e.g., $|I_p|$) received from the positive sequence current magnitude calculator **904**. As described above, the example interpolator **908** then identifies the four closest ones of the negative sequence voltage values **3002-3040** (e.g., the 4 nearest neighbors) based on Euclidean distance in the operating point space **3000** (e.g., in the positive sequence voltage magnitude, positive sequence current magnitude plane). Of the example negative sequence voltage values **3002-3040**, the 4 nearest neighbors to the current operating point **3042** are, from nearest to farthest, the point **3032**, the point **3028**, the point **3036**, and the point **3030**.

The example interpolator **908** determines that all 4 of the nearest neighbors **3032**, **3028**, **3036**, **3030** are within the threshold distance from the operating point **3042**. Accordingly, the interpolator **908** checks the co-linearity of the three nearest neighbors **3032**, **3028**, and **3036** using the example Equations 2-6 above, and determines that the points are not too co-linear.

The example interpolator **908** proceeds to fit a plane to the three nearest neighbors **3032**, **3028**, and **3036** using the example Equations 7-10 above. Using the calculated plane and the nearest point **3032**, the example interpolator **908** calculates an expected negative sequence voltage value for the current operating point **3042** using Equation 11 above. When the calculated expected negative sequence voltage value is an amplitude, the example interpolator **908** calculates the direct and quadrature values from the calculated expected negative sequence voltage value using the concurrent phase of the phase signals (e.g., from the data acquisition controller **912**).

While example manners of implementing the fault detection circuit **102**, **300** of FIGS. 1-3 are illustrated in FIGS. 9 and 10, one or more of the elements, processes and/or devices illustrated in FIGS. 9 and 10 may be combined, divided, re-arranged, omitted, eliminated and/or implemented in any other way. Further, the example positive sequence voltage magnitude calculators **902**, the example positive sequence current magnitude calculators **904**, the example negative sequence voltage calculators **906**, the example interpolator **908**, the example fault detector **910**, the example data acquisition controllers **912**, **2600**, the example learner **914**, the example Clarke transformers **918**, **928**, **1002**, **1004**, the example subtractors **944a**, **944b**, the example amplitude calculators **948**, **1110**, **1610**, the example high pass filter **952**, the example Park transformers **1102**, **1602**, the example windowers **1104**, **1604**, **2104**, the example integrators **1106**, **1606**, **2106**, the example positive sequence voltage magnitude buffer **1108**, the example positive sequence current magnitude buffer **1608**, the example negative sequence voltage buffer **2108**, the example low pass filter **2110**, the example zero crossing detector **2602**, the example angular change calculator **2606**, the example sample counter **2604**, the example sampling clock **2608**, the example phase angle calculator **2610**, the example window angle calculator **2612**, the example reset trigger **2614** and/or, more generally, the example fault detection circuits **102**, **300**, **900**, **1000** of FIGS. 1, 2, 3, 9, and/or 10 may be implemented by hardware, software, firmware and/or any combination of hardware, software and/or firmware. Thus, for example, any of the example positive sequence voltage magnitude calculators **902**, the example positive sequence current magnitude calculators **904**, the example negative sequence voltage calculators **906**, the example interpolator **908**, the example fault detector **910**, the example data acquisition controllers **912**, **2600**, the example learner **914**,

the example Clarke transformers **918**, **928**, **1002**, **1004**, the example subtractors **944a**, **944b**, the example amplitude calculators **948**, **1110**, **1610**, the example high pass filter **952**, the example Park transformers **1102**, **1602**, the example windowers **1104**, **1604**, **2104**, the example integrators **1106**, **1606**, **2106**, the example positive sequence voltage magnitude buffer **1108**, the example positive sequence current magnitude buffer **1608**, the example negative sequence voltage buffer **2108**, the example low pass filter **2110**, the example zero crossing detector **2602**, the example angular change calculator **2606**, the example sample counter **2604**, the example sampling clock **2608**, the example phase angle calculator **2610**, the example window angle calculator **2612**, the example reset trigger **2614** and/or, more generally, the example fault detection circuits **102**, **300**, **900**, **1000** could be implemented by one or more analog or digital circuit(s), logic circuits, programmable processor(s), application specific integrated circuit(s) (ASIC(s)), programmable logic device(s) (PLD(s)) and/or field programmable logic device(s) (FPLD(s)). When reading any of the apparatus or system claims of this patent to cover a purely software and/or firmware implementation, at least one of the example positive sequence voltage magnitude calculators **902**, the example positive sequence current magnitude calculators **904**, the example negative sequence voltage calculators **906**, the example interpolator **908**, the example fault detector **910**, the example data acquisition controllers **912**, **2600**, the example learner **914**, the example Clarke transformers **918**, **928**, **1002**, **1004**, the example subtractors **944a**, **944b**, the example amplitude calculators **948**, **1110**, **1610**, the example high pass filter **952**, the example Park transformers **1102**, **1602**, the example windowers **1104**, **1604**, **2104**, the example integrators **1106**, **1606**, **2106**, the example positive sequence voltage magnitude buffer **1108**, the example positive sequence current magnitude buffer **1608**, the example negative sequence voltage buffer **2108**, the example low pass filter **2110**, the example zero crossing detector **2602**, the example angular change calculator **2606**, the example sample counter **2604**, the example sampling clock **2608**, the example phase angle calculator **2610**, the example window angle calculator **2612**, and/or the example reset trigger **2614** is/are hereby expressly defined to include a tangible computer readable storage device or storage disk such as a memory, a digital versatile disk (DVD), a compact disk (CD), a Blu-ray disk, etc. storing the software and/or firmware. Further still, the example fault detection circuits **102**, **300**, **900**, **1000** of FIGS. 1, 2, 3, 9, and/or 10 may include one or more elements, processes and/or devices in addition to, or instead of, those illustrated in FIGS. 1, 2, 3, 9, and/or 10, and/or may include more than one of any or all of the illustrated elements, processes and devices.

Flowcharts representative of example machine readable instructions for implementing the fault detection circuits **102**, **300**, **900**, **1000** of FIGS. 1, 2, 3, 9, and/or 10 are shown in FIGS. 31A-31B, 32A-32B, 33A-33B, 34A-34B, 35A-35E, and 36. In this example, the machine readable instructions comprise program(s) for execution by a processor such as the processors **4512**, **4612** shown in the example processor platforms **4500**, **4600** discussed below in connection with FIGS. 45 and 46. The program(s) may be embodied in software stored on a tangible computer readable storage medium such as a CD-ROM, a floppy disk, a hard drive, a digital versatile disk (DVD), a Blu-ray disk, or a memory associated with the processors **4512**, **4612**, but the entire program(s) and/or parts thereof could alternatively be executed by a device other than the processors **4512**, **4612** and/or embodied in firmware or dedicated hardware. Fur-

ther, although the example program(s) are described with reference to the flowcharts illustrated in FIGS. 31A-31B, 32A-32B, 33A-33B, 34A-34B, 35A-35E, and 36, many other methods of implementing the example fault detection circuits 102, 300, 900, 1000 of FIGS. 1, 2, 3, 9, and/or 10 may alternatively be used. For example, the order of execution of the blocks may be changed, and/or some of the blocks described may be changed, eliminated, or combined.

As mentioned above, the example processes of FIGS. 31A-31B, 32A-32B, 33A-33B, 34A-34B, 35A-35E, and 36 may be implemented using coded instructions (e.g., computer and/or machine readable instructions) stored on a tangible computer readable storage medium such as a hard disk drive, a flash memory, a read-only memory (ROM), a compact disk (CD), a digital versatile disk (DVD), a cache, a random-access memory (RAM) and/or any other storage device or storage disk in which information is stored for any duration (e.g., for extended time periods, permanently, for brief instances, for temporarily buffering, and/or for caching of the information). As used herein, the term tangible computer readable storage medium is expressly defined to include any type of computer readable storage device and/or storage disk and to exclude propagating signals and transmission media. As used herein, “tangible computer readable storage medium” and “tangible machine readable storage medium” are used interchangeably. Additionally or alternatively, the example processes of FIGS. 31A-31B, 32A-32B, 33A-33B, 34A-34B, 35A-35E, and 36 may be implemented using coded instructions (e.g., computer and/or machine readable instructions) stored on a non-transitory computer and/or machine readable medium such as a hard disk drive, a flash memory, a read-only memory, a compact disk, a digital versatile disk, a cache, a random-access memory and/or any other storage device or storage disk in which information is stored for any duration (e.g., for extended time periods, permanently, for brief instances, for temporarily buffering, and/or for caching of the information). As used herein, the term non-transitory computer readable medium is expressly defined to include any type of computer readable storage device and/or storage disk and to exclude propagating signals and transmission media. As used herein, when the phrase “at least” is used as the transition term in a preamble of a claim, it is open-ended in the same manner as the term “comprising” is open ended.

FIG. 31A-31B is a flowchart representative of example machine readable instructions 3100 which may be executed to implement the example learner 914 of FIGS. 9 and/or 10 to conduct a training phase to store a set of training negative sequence voltage values corresponding to combinations of training positive sequence voltage magnitude values and training positive sequence current magnitude values. The example flowchart 3100 of FIG. 31A-31B may be executed to implement the example state machine 2700 of FIG. 27.

The example learner 914 of FIG. 9 is initialized (e.g., turned on, started) (block 3102). At initialization, the example learner 914 enters an idle state (e.g., the idle state 2702 of FIG. 27) (block 3104). In the idle state 2702, a start learning flag is not set. The example learner 914 determine whether the start learning flag has been set (block 3106). If the start learning flag has not been set (block 3106), the example learner 914 returns control to block 3104 to remain in the idle state.

When the start learning flag is set (block 3106), the learner 914 identifies that the motor is in a transient state (e.g., the transient state 2704 of FIG. 27) (block 3108). The motor may, in fact, be in a steady state when the start

learning flag is set, but the example learner 914 assumes that the motor is in the transient state 2704.

The example learner 914 measures the positive sequence voltage magnitude value 932 (e.g., $|V_p|$), the positive sequence current magnitude value 934 (e.g., $|I_p|$), and the negative sequence voltage values 936a, 936b (e.g., V_{nd} , V_{nq}) (block 3110). For example, the learner 914 may obtain the positive sequence voltage magnitude value 932 (e.g., $|V_p|$) from the positive sequence voltage magnitude calculator 902, the positive sequence current magnitude value 934 (e.g., $|I_p|$) from the positive sequence current magnitude calculator 904, and the negative sequence voltage values 936a, 936b (e.g., V_{nd} , V_{nq}) from the negative sequence voltage calculator 906, controlled by the data acquisition controller 912. Example instructions to implement block 3110 are described below with reference to FIGS. 35A-35E.

The example high pass filter 952 executes a high pass filter to filter the positive sequence voltage magnitude value 932 (e.g., $|V_p|$) to obtain a filtered positive sequence voltage magnitude value 954 (e.g., $|V_p|_{hp}$) and filters the positive sequence current magnitude value 934 (e.g., $|I_p|_{hp}$) to obtain a filtered positive sequence current magnitude value 956 (block 3112). The example learner 914 determines whether the filtered positive sequence voltage magnitude value 954 (e.g., $|V_p|_{hp}$) is greater than (or equal to) a threshold value (e.g., ϵ_{TH}) (block 3114). If the filtered positive sequence voltage magnitude value 954 (e.g., $|V_p|_{hp}$) is not greater than (or equal to) the threshold value (e.g., ϵ_{TH}) (block 3114), the example learner 914 determines whether the positive sequence current magnitude value 956 (e.g., $|I_p|_{hp}$) is greater than (or equal to) a threshold value (e.g., ϵ_{TH}) (block 3116).

When the filtered positive sequence current magnitude value 956 (e.g., $|I_p|_{hp}$) is not greater than (or equal to) a threshold value (e.g., ϵ_{TH}) (block 3116), the example learner 914 determines whether a threshold timer has elapsed (block 3118). For example, the learner 914 may determine whether a time T has reached a threshold time T_{TH} . If the threshold timer has not elapsed (block 3118), control returns to block 3110 to repeat the measurements of the positive sequence voltage magnitude value 932 (e.g., $|V_p|$), the positive sequence current magnitude value 934 (e.g., $|I_p|$), and the negative sequence voltage values 936a, 936b (e.g., V_{nd} , V_{nq}).

On the other hand, if the threshold timer has elapsed (block 3118), the example learner 914 identifies a nearest neighbor (x_1 , y_1) in the a baseline table (e.g., the baseline table 940 of FIGS. 9 and/or 10) to the current operating point (x_0 , y_0) (block 3120). The current operating point used in block 3120 refers to a combination of the positive sequence voltage magnitude value 932 (e.g., $|V_p|$) and the positive sequence current magnitude value 934 (e.g., $1/A$) measured in block 3110. The nearest neighbor (x_1 , y_1) refers to a combination of the positive sequence voltage magnitude value 932 (e.g., $|V_p|$) and the positive sequence current magnitude value 934 (e.g., $|I_p|$) stored in the baseline table 940 that has a corresponding negative sequence voltage value and has a shortest Euclidean distance to the current operating point (x_0 , y_0) in the x, y plane.

The example learner 914 determines whether a distance d between the current operating point (x_0 , y_0) and the nearest neighbor (x_1 , y_1) is less than (or equal to) a threshold distance d_{TH} (block 3122). For example, the learner 914 may determine whether the Euclidean distance between the current operating point (x_0 , y_0) and the nearest neighbor (x_1 , y_1) in the x, y plane (e.g., using the Pythagorean theorem) is less than or equal to the threshold distance d_{TH} .

If the distance d between the current operating point (x_0, y_0) and the nearest neighbor (x_1, y_1) is greater than the threshold distance d_{TH} (block 3122), the example learner 914 determines whether a size s of the baseline table 940 (e.g., in numbers of stored combinations) is less than a threshold size s_{TH} (block 3124). If the size s of the baseline table 940 is less than the threshold size s_{TH} (block 3124), the example learner 914 adds a point to the baseline table 940 that includes the combination of the positive sequence voltage magnitude value 932 (e.g., $|V_p|$), the positive sequence current magnitude value 934 (e.g., $|I_p|$), and the negative sequence voltage values 936a, 936b (e.g., V_{nd}, V_{nq}) and/or an amplitude of the negative sequence voltage values 936a, 936b (e.g., $|V_p|, |I_p|, V_{nd}, V_{nq}$ and/or $|V_p|, |I_p|, |V_n|$) (block 3126).

After storing the point (block 3126), if the size s of the baseline table 940 is at least the threshold size s_{TH} (block 3124), or if the distance d between the current operating point (x_0, y_0) and the nearest neighbor (x_1, y_1) is less than or equal to the threshold distance d_{TH} (block 3122), the example learner 914 identifies that the motor is in a stable state (or steady state) (block 3128). The stable state of block 3128 corresponds to the example stable state 2706 of FIG. 27.

The example learner 914 measures the positive sequence voltage magnitude value 932 (e.g., $|V_p|$) and the positive sequence current magnitude value 934 (e.g., $|I_p|$) (block 3130). The example high pass filter 952 executes a high pass filter to filter the positive sequence voltage magnitude value 932 (e.g., $|V_p|$) to obtain a filtered positive sequence voltage magnitude value 954 (e.g., $|V_p|_{hp}$) and filters the positive sequence current magnitude value 934 (e.g., $|I_p|_{hp}$) to obtain a filtered positive sequence current magnitude value 956 (block 3132). The example learner 914 determines whether the filtered positive sequence voltage magnitude value 954 (e.g., $|V_p|_{hp}$) is greater than (or equal to) the threshold value (e.g., ϵ_{TH}) (block 3134). If the filtered positive sequence voltage magnitude value 954 (e.g., $|V_p|_{hp}$) is not greater than (or equal to) the threshold value (e.g., ϵ_{TH}) (block 3134), the example learner 914 determines whether the filtered positive sequence current magnitude value 956 (e.g., $|I_p|_{hp}$) is greater than (or equal to) a threshold value (e.g., ϵ_{TH}) (block 3136).

When either of the filtered positive sequence voltage magnitude value 954 (e.g., $|V_p|_{hp}$) is greater than (or equal to) the threshold value (e.g., ϵ_{TH}) (block 3134) or the positive sequence current magnitude value 956 (e.g., $|I_p|_{hp}$) is greater than (or equal to) a threshold value (e.g., ϵ_{TH}) (block 3136), the learner 914 identifies that the motor is in a transient state and returns control to block 3108.

When the filtered positive sequence voltage magnitude value 954 (e.g., $|V_p|_{hp}$) is less than the threshold value (e.g., ϵ_{TH}) (block 3134) and the filtered positive sequence current magnitude value 956 (e.g., $|I_p|_{hp}$) is less than the threshold value (e.g., ϵ_{TH}) (block 3136), the example learner 914 determines whether a stop learning flag has been set (block 3138). If the stop learning flag has not been set (block 3138), the learner 914 returns control to block 3128 and remains in the stable state 2706.

On the other hand, if the stop learning flag has been set (block 3138), the example learner 914 returns to the idle state 2702 and returns control to block 3104.

When, in the transient state 2704, either of the filtered positive sequence voltage magnitude value 954 (e.g., $|V_p|_{hp}$) is greater than (or equal to) the threshold value (e.g., ϵ_{TH}) (block 3114) or the filtered positive sequence current magnitude value 956 (e.g., $|I_p|_{hp}$) is greater than (or equal to) a

threshold value (e.g., ϵ_{TH}) (block 3116), the example learner 914 resets the threshold timer T (block 3140).

The example learner 914 determines whether a stop learning flag has been set (block 3142). If the stop learning flag has not been set (block 3142), the learner 914 returns control to block 3108 and remains in the transient state 2704. On the other hand, if the stop learning flag has been set (block 3138), the example learner 914 returns to the idle state 2702 and returns control to block 3104.

FIG. 32A-32B is a flowchart representative of example machine readable instructions 3200 which may be executed to implement the example learner 914 of FIGS. 9 and/or 10 to conduct a training phase to calculate weights or coefficients for an interpolation equation to estimate expected negative sequence voltage values based on combinations of positive sequence voltage magnitude values and positive sequence current magnitude values.

The example learner 914 of FIG. 9 is initialized (e.g., turned on, started) (block 3202). At initialization, the example learner 914 enters an idle state (e.g., the idle state 2702 of FIG. 27) (block 3204). In the idle state 2702, a start learning flag is not set. The example learner 914 determines whether the start learning flag has been set (block 3206). If the start learning flag has not been set (block 3206), the example learner 914 returns control to block 3204 to remain in the idle state.

When the start learning flag is set (block 3206), the learner 914 identifies that the motor is in a transient state (e.g., the transient state 2704 of FIG. 27) (block 3208). The motor may, in fact, be in a steady state when the start learning flag is set, but the example learner 914 assumes that the motor is in the transient state 2704.

The example learner 914 measures the positive sequence voltage magnitude value 932 (e.g., $|V_p|$), the positive sequence current magnitude value 934 (e.g., $|I_p|$), and the negative sequence voltage values 936a, 936b (e.g., V_{nd}, V_{nq}) (block 3210). For example, the learner 914 may obtain the positive sequence voltage magnitude value 932 (e.g., $|V_p|$) from the positive sequence voltage magnitude calculator 902, the positive sequence current magnitude value 934 (e.g., $|I_p|$) from the positive sequence current magnitude calculator 904, and the negative sequence voltage values 936a, 936b (e.g., V_{nd}, V_{nq}) from the negative sequence voltage calculator 906, controlled by the data acquisition controller 912. Example instructions to implement block 3210 are described below with reference to FIGS. 35A-35E.

The example high pass filter 952 executes a high pass filter to filter the positive sequence voltage magnitude value 932 (e.g., $|V_p|$) to obtain a filtered positive sequence voltage magnitude value 954 (e.g., $|V_p|_{hp}$) and filters the positive sequence current magnitude value 934 (e.g., $|I_p|_{hp}$) to obtain a filtered positive sequence current magnitude value 956 (block 3212). The example learner 914 determines whether the filtered positive sequence voltage magnitude value 954 (e.g., $|V_p|_{hp}$) is greater than (or equal to) a threshold value (e.g., ϵ_{TH}) (block 3214). If the filtered positive sequence voltage magnitude value 954 (e.g., $|V_p|_{hp}$) is not greater than (or equal to) the threshold value (e.g., ϵ_{TH}) (block 3214), the example learner 914 determines whether the filtered positive sequence current magnitude value 956 (e.g., $|I_p|_{hp}$) is greater than (or equal to) a threshold value (e.g., ϵ_{TH}) (block 3216).

When the filtered positive sequence current magnitude value 956 (e.g., $|I_p|_{hp}$) is not greater than (or equal to) a threshold value (e.g., ϵ_{TH}) (block 3216), the example learner 914 determines whether a threshold timer has elapsed (block 3218). For example, the learner 914 may determine whether

a time T has reached a threshold time T_{TH} . If the threshold timer has not elapsed (block **3218**), control returns to block **3210** to repeat the measurements of the positive sequence voltage magnitude value **932** (e.g., $|V_p|$), the positive sequence current magnitude value **934** (e.g., $|I_p|$), and the negative sequence voltage values **936a**, **936b** (e.g., V_{nd} , V_{nq}).

On the other hand, if the threshold timer has elapsed (block **3218**), the example learner **914** identifies a nearest neighbor (x_1, y_1) in a list of operating points (e.g., (x_a, y_a) , (x_b, y_b) , etc.) to the current operating point (x_0, y_0) (block **3220**). Each of the operating points in the list of operating points further corresponds to one or more negative sequence voltage values. The current operating point used in block **3220** refers to a combination of the positive sequence voltage magnitude value **932** (e.g., $|V_p|$) and the positive sequence current magnitude value **934** (e.g., $|I_p|$) measured in block **3210**. The nearest neighbor (x_1, y_1) refers to a combination of the positive sequence voltage magnitude value **932** (e.g., $|V_p|$) and the positive sequence current magnitude value **934** (e.g., $|I_p|$) stored in the list of operating points that has a corresponding negative sequence voltage value and has a shortest Euclidean distance to the current operating point (x_0, y_0) in the x, y plane.

The example learner **914** determines whether a distance d between the current operating point (x_0, y_0) and the nearest neighbor (x_1, y_1) is less than (or equal to) a threshold distance d_{TH} (block **3222**). For example, the learner **914** may determine whether the Euclidean distance between the current operating point (x_0, y_0) and the nearest neighbor (x_1, y_1) in the x, y plane (e.g., using the Pythagorean theorem) is less than or equal to the threshold distance d_{TH} .

If the distance d between the current operating point (x_0, y_0) and the nearest neighbor (x_1, y_1) is greater than the threshold distance d_m (block **3222**), the example learner **914** determines whether a size s of the list of operating points (e.g., in numbers of stored combinations) is less than a threshold size s_{TH} (block **3224**). If the size s of the list of operating points is less than the threshold size s_{TH} (block **3224**), the example learner **914** adds a point to the list of operating points that includes the combination of the positive sequence voltage magnitude value **932** (e.g., $|V_p|$), the positive sequence current magnitude value **934** (e.g., $|I_p|$), and the negative sequence voltage values **936a**, **936b** (e.g., V_{nd} , V_{nq}) and/or an amplitude of the negative sequence voltage values **936a**, **936b** (e.g., $|V_p|$, $|I_p|$, V_{nd} , V_{nq} and/or $|V_p|$, $|I_p|$, $|V_n|$) (block **3226**).

After storing the point (block **3226**), if the size s of the baseline table **940** is at least the threshold size s_{TH} (block **3224**), or if the distance d between the current operating point (x_0, y_0) and the nearest neighbor (x_1, y_1) is less than or equal to the threshold distance d_{TH} (block **3222**), the example learner **914** identifies that the motor is in a stable state (or steady state) (block **3228**). The stable state of block **3228** corresponds to the example stable state **2706** of FIG. **27**.

While in the stable state **2706**, the example learner **914** determines whether the size s of the list of operating points is greater than or equal to the threshold size (block **3230**). If the size s of the list of operating points is greater than or equal to the threshold size (block **3230**), the example learner **914** calculates coefficients of an interpolation equation using the list of operating points (block **3232**). For example, the learner **914** may attempt to fit one or more types of equations (e.g., polynomial equations) to the list of operating points, by calculating appropriate coefficients for the polynomial terms (e.g., a_0 - a_8 of Equation 1 above). The example learner

914 attempts to find a best fit equation having less than a threshold error compared to the list of the operating points. After calculating the coefficients (block **3232**), the example learner **914** returns control to block **3204** and enters the idle state **3204**.

If the size s of the list of operating points is less than the threshold size (block **3230**), the example learner **914** measures the positive sequence voltage magnitude value **932** (e.g., $|V_p|$) and the positive sequence current magnitude value **934** (e.g., $|I_p|$) (block **3234**). The example high pass filter **952** executes a high pass filter to filter the positive sequence voltage magnitude value **932** (e.g., $|V_p|$) to obtain a filtered positive sequence voltage magnitude value **954** (e.g., $|V_p|_{hp}$) and filters the positive sequence current magnitude value **934** (e.g., $|I_p|_{hp}$) to obtain a filtered positive sequence current magnitude value **956** (block **3236**). The example learner **914** determines whether the filtered positive sequence voltage magnitude value **954** (e.g., $|V_p|_{hp}$) is greater than (or equal to) the threshold value (e.g., ϵ_{TH}) (block **3238**). If the filtered positive sequence voltage magnitude value **954** (e.g., $|V_p|_{hp}$) is not greater than (or equal to) the threshold value (e.g., ϵ_{TH}) (block **3238**), the example learner **914** determines whether the filtered positive sequence current magnitude value **956** (e.g., $|I_p|_{hp}$) is greater than (or equal to) a threshold value (e.g., ϵ_{TH}) (block **3240**).

When either of the filtered positive sequence voltage magnitude value **954** (e.g., $|V_p|_{hp}$) is greater than (or equal to) the threshold value (e.g., ϵ_{TH}) (block **3238**) or the filtered positive sequence current magnitude value **956** (e.g., $|I_p|_{hp}$) is greater than (or equal to) a threshold value (e.g., ϵ_{TH}) (block **3240**), the learner **914** identifies that the motor is in a transient state and returns control to block **3208**.

When the filtered positive sequence voltage magnitude value **954** (e.g., $|V_p|_{hp}$) is less than the threshold value (e.g., ϵ_{TH}) (block **3238**) and the filtered positive sequence current magnitude value **956** (e.g., $|I_p|_{hp}$) is less than the threshold value (e.g., ϵ_{TH}) (block **3240**), the example learner **914** determines whether a stop learning flag has been set (block **3242**). If the stop learning flag has not been set (block **3242**), the learner **914** returns control to block **3228** and remains in the stable state **2706**.

On the other hand, if the stop learning flag has been set (block **3242**), the example learner **914** returns to the idle state **2702** and returns control to block **3204**.

When, in the transient state **2704**, either of the filtered positive sequence voltage magnitude value **954** (e.g., $|V_p|_{hp}$) is greater than (or equal to) the threshold value (e.g., ϵ_{TH}) (block **3214**) or the filtered positive sequence current magnitude value **956** (e.g., $|I_p|_{hp}$) is greater than (or equal to) a threshold value (e.g., ϵ_{TH}) (block **3216**), the example learner **914** resets the threshold timer T (block **3244**).

The example learner **914** determines whether a stop learning flag has been set (block **3246**). If the stop learning flag has not been set (block **3246**), the learner **914** returns control to block **3208** and remains in the transient state **2704**. On the other hand, if the stop learning flag has been set (block **3246**), the example learner **914** returns to the idle state **2702** and returns control to block **3204**.

FIG. **33** is a flowchart representative of example machine readable instructions **3300** which may be executed to implement the example fault detection circuits **900**, **1000** of FIGS. **9** and/or **10** to detect an winding fault in a motor during a protection phase based on a stored set of negative sequence voltage values corresponding to combinations of positive sequence voltage magnitude values and positive sequence current magnitude values. The example instructions **3300** may be partially implemented by the fault detector **910**

executing the state machine **1200** of FIG. **12** to perform a protection phase of the fault detection circuit **900**, **1000**.

The example fault detection circuit **900**, **1000** measures the positive sequence voltage magnitude value **932** (e.g., $|V_p|$), the positive sequence current magnitude value **934** (e.g., $|I_p|$), and the negative sequence voltage values **936a**, **936b** (e.g., V_{nd} , V_{nq}) (block **3304**). For example, the fault detector **910** may obtain the positive sequence voltage magnitude value **932** (e.g., $|V_p|$) from the positive sequence voltage magnitude calculator **902**, the positive sequence current magnitude value **934** (e.g., $|I_p|$) from the positive sequence current magnitude calculator **904**, and the negative sequence voltage values **936a**, **936b** (e.g., V_{nd} , V_{nq}) from the negative sequence voltage calculator **906**, controlled by the data acquisition controller **912**. Example instructions to implement block **3304** are described below with reference to FIGS. **35A-35E**.

The example high pass filter **952** executes a high pass filter to filter the positive sequence voltage magnitude value **932** (e.g., $|V_p|$) to obtain a filtered positive sequence voltage magnitude value **954** (e.g., $|V_p|_{hp}$) and filters the positive sequence current magnitude value **934** (e.g., $|I_p|_{hp}$) to obtain a filtered positive sequence current magnitude value **956** (block **3306**). The example fault detector **910** determines whether the filtered positive sequence voltage magnitude value **954** (e.g., $|V_p|_{hp}$) is greater than (or equal to) a threshold value (e.g., ϵ_{TH}) (block **3308**). If the filtered positive sequence voltage magnitude value **954** (e.g., $|V_p|_{hp}$) is not greater than (or equal to) the threshold value (e.g., ϵ_{TH}) (block **3308**), the example learner **914** determines whether the filtered positive sequence current magnitude value **956** (e.g., $|I_p|_{hp}$) is greater than (or equal to) a threshold value (e.g., ϵ_{TH}) (block **3310**).

When, in the transient state **1202**, either of the filtered positive sequence voltage magnitude value **954** (e.g., $|V_p|_{hp}$) is greater than (or equal to) the threshold value (e.g., ϵ_{TH}) (block **3308**) or the positive sequence current magnitude value **956** (e.g., $|I_p|_{hp}$) is greater than (or equal to) a threshold value (e.g., ϵ_{TH}) (block **3310**), the example fault detector **910** resets a threshold timer T (block **3312**). The fault detector **910** then returns control to block **3302** to remain in the transient state **1202**.

On the other hand, when the filtered positive sequence current magnitude value **956** (e.g., $|I_p|_{hp}$) is not greater than (or equal to) the threshold value (e.g., ϵ_{TH}) (block **3310**), the example fault detector **910** determines whether the threshold timer has elapsed (block **3314**). For example, the learner **914** may determine whether a time T counted by the threshold timer has reached a threshold time T_{TH} . If the threshold timer has not elapsed (block **3314**), control returns to block **3304** to repeat the measurements of the positive sequence voltage magnitude value **932** (e.g., $|V_p|$), the positive sequence current magnitude value **934** (e.g., $|I_p|$), and the negative sequence voltage values **936a**, **936b** (e.g., V_{nd} , V_{nq}).

If the threshold timer has elapsed (block **3314**), the example fault detector **910** identifies that the motor is in a stable state in block **3316** of FIG. **33B**. The stable state of block **3316** corresponds to the stable state **1204** of FIG. **12**.

The example fault detection circuit **900**, **1000** measures the positive sequence voltage magnitude value **932** (e.g., $|V_p|$), the positive sequence current magnitude value **934** (e.g., $|I_p|$), and the negative sequence voltage values **936a**, **936b** (e.g., V_{nd} , V_{nq}) (block **3318**). For example, the fault detector **910** may obtain the positive sequence voltage magnitude value **932** (e.g., $|V_p|$) from the positive sequence voltage magnitude calculator **902**, the positive sequence

current magnitude value **934** (e.g., $|I_p|$) from the positive sequence current magnitude calculator **904**, and the negative sequence voltage values **936a**, **936b** (e.g., V_{nd} , V_{nq}) from the negative sequence voltage calculator **906**, controlled by the data acquisition controller **912**. Example instructions to implement block **3318** are described below with reference to FIGS. **35A-35E**.

The example high pass filter **952** executes a high pass filter to filter the positive sequence voltage magnitude value **932** (e.g., $|V_p|$) to obtain a filtered positive sequence voltage magnitude value **954** (e.g., $|V_p|_{hp}$) and filters the positive sequence current magnitude value **934** (e.g., $|I_p|_{hp}$) to obtain a filtered positive sequence current magnitude value **956** (block **3320**). The example fault detector **910** determines whether the filtered positive sequence voltage magnitude value **954** (e.g., $|V_p|_{hp}$) is greater than (or equal to) a threshold value (e.g., ϵ_{TH}) (block **3322**). If the filtered positive sequence voltage magnitude value **954** (e.g., $|V_p|_{hp}$) is not greater than (or equal to) the threshold value (e.g., ϵ_{TH}) (block **3322**), the example learner **914** determines whether the filtered positive sequence current magnitude value **956** (e.g., $|I_p|_{hp}$) is greater than (or equal to) a threshold value (e.g., ϵ_{TH}) (block **3324**).

When, in the stable state **1204**, either of the filtered positive sequence voltage magnitude value **954** (e.g., $|V_p|_{hp}$) is greater than (or equal to) the threshold value (e.g., ϵ_{TH}) (block **3322**) or the positive sequence current magnitude value **956** (e.g., $|I_p|_{hp}$) is greater than (or equal to) a threshold value (e.g., ϵ_{TH}) (block **3324**), the example fault detector **910** returns control to block **3302** to return to the transient state **1202**.

On the other hand, when the filtered positive sequence current magnitude value **956** (e.g., $|I_p|_{hp}$) is not greater than (or equal to) the threshold value (e.g., ϵ_{TH}) (block **3324**), the example interpolator **908** selects the 3 nearest neighbor points to the current operating point ($|V_p|$, $|I_p|$) or (x_0, y_0) from the baseline table **940** (block **3326**). For example, the interpolator **908** may determine Euclidean distances between the current operating point (x_0, y_0) and the other points in the baseline table **940** and select the 3 points in the baseline table with the shortest distances (e.g., (x_1, y_1) , (x_2, y_2) , and (x_3, y_3)). The example interpolator **908** determines whether the selected nearest neighbors (x_1, y_1) , (x_2, y_2) , and (x_3, y_3) are too co-linear (block **3328**). For example, the interpolator **908** may use Equations 2-6 above, and/or fit a line between the first nearest neighbor (x_1, y_1) and the third nearest neighbor (x_3, y_3) , and then determine whether the second nearest neighbor (x_2, y_2) is less than a threshold distance from the line.

If the selected nearest neighbors are too close to being co-linear (block **3328**), the example interpolator **908** selects the 2nd, 3rd, and 4th nearest neighbor points to the current operating point ($|V_p|_{hp}$, $|I_p|$) or (x_0, y_0) from the baseline table **940** (block **3330**). For example, the interpolator **908** may determine Euclidean distances between the current operating point (x_0, y_0) and the other points in the baseline table **940** (or use the distances determined in block **3326**) and select the points in the baseline table with the 2nd, 3rd, and 4th shortest distances (e.g., (x_2, y_2) , (x_3, y_3) , and (x_4, y_4)). The example interpolator **908** determines whether the selected nearest neighbors (x_2, y_2) , (x_3, y_3) , and (x_4, y_4) are too co-linear (block **3332**). For example, the interpolator **908** may use Equations 2-6 above, and/or fit a line between the second nearest neighbor (x_2, y_2) and the fourth nearest neighbor (x_4, y_4) , and then determine whether the third nearest neighbor (x_3, y_3) is less than the threshold distance from the line.

If the first selected nearest neighbors are not too co-linear (block 3328) or the second selected nearest neighbors are not too co-linear (block 3332), the example interpolator 908 fits a plane to the selected nearest neighbors (block 3334). For example, if the first selected nearest neighbors (x_1, y_1) , (x_2, y_2) , and (x_3, y_3) are not too co-linear (block 3328), the interpolator 908 fits a plane to the first selected nearest neighbors. Alternatively, if the first selected nearest neighbors (x_1, y_1) , (x_2, y_2) , and (x_3, y_3) are too co-linear (block 3328) but the second selected nearest neighbors (x_2, y_2) , (x_3, y_3) , and (x_4, y_4) are not too co-linear (block 3332), the interpolator 908 fits a plane to the second selected nearest neighbors. The example interpolator 908 may calculate the plane using the example Equations 7-10 above.

The example interpolator 908 calculates an expected negative sequence voltage value V_{ne} (or a direct expected negative sequence voltage value 938a and quadrature expected negative sequence voltage value 938b, which are the components of the expected negative sequence voltage value V_{ne}) using the plane and the current operating point $(|V_p|, |I_p|)$ (block 3336). The calculated plane defines negative sequence voltage values V_n for any point on the plane. For example, the interpolator 908 may determine a negative sequence voltage value corresponding to the point on the plane on which the current operating point $(|V_p|, |I_p|)$ lies. The example interpolator 908 may use the example Equation 11 above to calculate the negative sequence voltage value(s). In some examples, the interpolator 908 determines an amplitude of the expected negative sequence voltage value V_{ne} and calculates the direct and quadrature components of the expected negative sequence voltage value V_{ne} from the amplitude and a phase angle (e.g., the phase angle being determined from the direct and quadrature components of the positive sequence voltage magnitude calculator 902).

The example subtractors 944a, 944b determine a difference value 946 between the expected negative sequence voltage values V_{nde} and V_{nqe} and the measured negative sequence voltage values V_{nd} and V_{nq} (block 3338). The example fault detector 910 determines whether the difference value 946 is greater than or equal to a threshold difference (block 3340). If the difference value 946 is greater than or equal to a threshold difference (block 3340), the example fault detector 910 increments a fault counter (block 3342). The fault detector 910 then determines whether the value of the fault counter is greater than or equal to a threshold count (block 3344).

If the value of the fault counter is greater than or equal to a threshold count (block 3344), the example fault detector 910 outputs the fault signal 958 (block 3346). Outputting the fault signal corresponds to the example fault state 1206 of FIG. 12. The example fault signal 958 may provide an alert to a motor controller (e.g., the motor controller 110 of FIGS. 1 and/or 2) and/or to an output to alert an operator of the detected winding fault. The fault detector 910 determines whether the fault signal has been reset (block 3348). For example, the fault detector 910 may receive an input that resets a fault flag and causes the fault detector 910 to return to the transient state 1202. If the fault signal has not been reset (block 3348), the example fault detector 910 remains in the fault state 1206 and returns control to block 3346. If the fault signal has been reset (block 3348), the example fault detector returns to the transient state 1202 and returns control to block 3302.

If the difference value 946 is less than the threshold difference (block 3340), the example fault detector 910 resets the fault counter (block 3350). After resetting the fault counter (block 3350), or if the value of the fault counter is

less than the threshold count (block 3344), the example fault detector 910 returns control to block 3316 and remains in the stable state 1204).

If the 2nd, 3rd, and 4th nearest neighbors are too close to co-linear (block 3332), the example interpolator 908 determines whether the nearest neighbor point (x_1, y_1) is less than a threshold distance from the current operating point $(|V_p|, |I_p|)$ (block 3352). If the nearest neighbor point (x_1, y_1) is less than a threshold distance from the current operating point $(|V_p|, |I_p|)$, the example interpolator 908 uses the nearest neighbor point (x_1, y_1) to determine the expected negative sequence voltage values 938a, 938b (V_{nde} and V_{nqe}) (block 3354). The example interpolator 908 then passes control to block 3338 to determine a difference value 946 between the expected negative sequence voltage values V_{nde} and V_{nqe} and the measured negative sequence voltage values V_{nd} and V_{nq} .

If the nearest neighbor point (x_1, y_1) is not less than the threshold distance from the current operating point $(|V_p|, |I_p|)$ (block 3352), the example fault detection circuit 900, 1000 may be disabled until the current operating point changes. The example interpolator 908 determines whether the current operating point $(|V_p|, |I_p|)$ has changed (block 3356). While the current operating point $(|V_p|, |I_p|)$ does not change, the example interpolator 908 loops block 3356. When the current operating point $(|V_p|, |I_p|)$ changes (block 3356), or when the fault signal is reset (block 3348), the example fault detector 910 returns to the transient state 1202 and the fault detection circuit 900, 1000 returns control to block 3302.

FIG. 34 is a flowchart representative of example machine readable instructions which may be executed to implement the example fault detection circuits 900, 1000 of FIGS. 9 and/or 10 to detect an winding fault in a motor during a protection phase using an interpolation equation to estimate expected negative sequence voltage values based on combinations of positive sequence voltage magnitude values and positive sequence current magnitude values. The example instructions 3400 may be partially implemented by the fault detector 910 executing the state machine 1200 of FIG. 12 to perform a protection phase of the fault detection circuit 900, 1000.

The example fault detector 910 initially identifies that the motor under protection (e.g., the three-phase motor 106 of FIGS. 1-3) is in a transient state (block 3402). For example, the fault detector 910 may begin the protection phase in the transient state 1202 of FIG. 12.

The example fault detection circuit 900, 1000 measures the positive sequence voltage magnitude value 932 (e.g., $|V_p|$), the positive sequence current magnitude value 934 (e.g., $|I_p|$), and the negative sequence voltage values 936a, 936b (e.g., V_{nd} , V_{nq}) (block 3404). For example, the fault detector 910 may obtain the positive sequence voltage magnitude value 932 (e.g., $|V_p|$) from the positive sequence voltage magnitude calculator 902, the positive sequence current magnitude value 934 (e.g., $|I_p|$) from the positive sequence current magnitude calculator 904, and the negative sequence voltage values 936a, 936b (e.g., V_{nd} , V_{nq}) from the negative sequence voltage calculator 906, controlled by the data acquisition controller 912. Example instructions to implement block 3404 are described below with reference to FIGS. 35A-35E.

The example high pass filter 952 executes a high pass filter to filter the positive sequence voltage magnitude value 932 (e.g., $|V_p|$) to obtain a filtered positive sequence voltage magnitude value 954 (e.g., $|V_p|_{hp}$) and filters the positive sequence current magnitude value 934 (e.g., $|I_p|_{hp}$) to obtain

a filtered positive sequence current magnitude value **956** (block **3406**). The example fault detector **910** determines whether the filtered positive sequence voltage magnitude value **954** (e.g., $|V_p|_{hp}$) is greater than (or equal to) a threshold value (e.g., ε_{TH}) (block **3408**). If the filtered positive sequence voltage magnitude value **954** (e.g., $|V_p|_{hp}$) is not greater than (or equal to) the threshold value (e.g., ε_{TH}) (block **3408**), the example learner **914** determines whether the filtered positive sequence current magnitude value **956** (e.g., $|I_p|_{hp}$) is greater than (or equal to) a threshold value (e.g., ε_{TH}) (block **3410**).

When, in the transient state **1202**, either of the filtered positive sequence voltage magnitude value **954** (e.g., $|V_p|_{hp}$) is greater than (or equal to) the threshold value (e.g., ε_{TH}) (block **3408**) or the positive sequence current magnitude value **956** (e.g., $|I_p|_{hp}$) is greater than (or equal to) a threshold value (e.g., ε_{TH}) (block **3410**), the example fault detector **910** resets a threshold timer T (block **3412**). The fault detector **910** then returns control to block **3402** to remain in the transient state **1202**.

On the other hand, when the filtered positive sequence current magnitude value **956** (e.g., $|I_p|_{hp}$) is not greater than (or equal to) the threshold value (e.g., ε_{TH}) (block **3410**), the example fault detector **910** determines whether the threshold timer has elapsed (block **3414**). For example, the learner **914** may determine whether a time T counted by the threshold timer has reached a threshold time T_{TH} . If the threshold timer has not elapsed (block **3414**), control returns to block **3404** to repeat the measurements of the positive sequence voltage magnitude value **932** (e.g., $|V_p|$), the positive sequence current magnitude value **934** (e.g., $|I_p|$), and the negative sequence voltage values **936a**, **936b** (e.g., V_{nd} , V_{nq}).

If the threshold timer has elapsed (block **3414**), the example fault detector **910** identifies that the motor is in a stable state in block **3416** of FIG. **34B**. The stable state of block **3416** corresponds to the stable state **1204** of FIG. **12**.

The example fault detection circuit **900**, **1000** measures the positive sequence voltage magnitude value **932** (e.g., $|V_p|$), the positive sequence current magnitude value **934** (e.g., $|I_p|$), and the negative sequence voltage values **936a**, **936b** (e.g., V_{nd} , V_{nq}) (block **3418**). For example, the fault detector **910** may obtain the positive sequence voltage magnitude value **932** (e.g., $|V_p|$) from the positive sequence voltage magnitude calculator **902**, the positive sequence current magnitude value **934** (e.g., $|I_p|$) from the positive sequence current magnitude calculator **904**, and the negative sequence voltage values **936a**, **936b** (e.g., V_{nd} , V_{nq}) from the negative sequence voltage calculator **906**, controlled by the data acquisition controller **912**. Example instructions to implement block **3418** are described below with reference to FIGS. **35A-35E**.

The example high pass filter **952** executes a high pass filter to filter the positive sequence voltage magnitude value **932** (e.g., $|V_p|$) to obtain a filtered positive sequence voltage magnitude value **954** (e.g., $|V_p|_{hp}$) and filters the positive sequence current magnitude value **934** (e.g., $|I_p|_{hp}$) to obtain a filtered positive sequence current magnitude value **956** (block **3420**). The example fault detector **910** determines whether the filtered positive sequence voltage magnitude value **954** (e.g., $|V_p|_{hp}$) is greater than (or equal to) a threshold value (e.g., ε_{TH}) (block **3422**). If the filtered positive sequence voltage magnitude value **954** (e.g., $|V_p|_{hp}$) is not greater than (or equal to) the threshold value (e.g., ε_{TH}) (block **3422**), the example learner **914** determines whether

the filtered positive sequence current magnitude value **956** (e.g., $|I_p|_{hp}$) is greater than (or equal to) a threshold value (e.g., ε_{TH}) (block **3424**).

When, in the stable state **1204**, either of the filtered positive sequence voltage magnitude value **954** (e.g., $|V_p|_{hp}$) is greater than (or equal to) the threshold value (e.g., ε_{TH}) (block **3422**) or the positive sequence current magnitude value **956** (e.g., $|I_p|_{hp}$) is greater than (or equal to) a threshold value (e.g., ε_{TH}) (block **3424**), the example fault detector **910** returns control to block **3402** to return to the transient state **1202**.

On the other hand, when the filtered positive sequence current magnitude value **956** (e.g., $|I_p|_{hp}$) is not greater than (or equal to) the threshold value (e.g., ε_{TH}) (block **3424**), the example interpolator **908** calculates an expected negative sequence voltage value V_{ne} (or a direct expected negative sequence voltage value **938a** and quadrature expected negative sequence voltage value **938b**, which are the components of the expected negative sequence voltage value V_{ne}) using the plane and the current operating point ($|V_p|$, $|I_p|$) (block **3426**). For example, the interpolator **908** may calculate a result of the interpolation equation determined by the learner **9124** using the current operating point, including the positive sequence voltage magnitude value **932** (e.g., $|V_p|$) and the positive sequence current magnitude value **934** (e.g., $|I_p|$). In some examples, the interpolator **908** determines an amplitude of the expected negative sequence voltage value $|V_n|_e$ using the interpolation equation and calculates the direct and quadrature components of the expected negative sequence voltage value $|V_n|_e$ from the amplitude and a phase angle (e.g., the phase angle being determined from the direct and quadrature components of the positive sequence voltage magnitude calculator **902**).

The example subtractors **944a**, **944b** determine a difference value **946** between the expected negative sequence voltage values V_{nde} and V_{nqe} and the measured negative sequence voltage values V_{nd} and V_{nq} (block **3428**). The example fault detector **910** determines whether the difference value **946** is greater than or equal to a threshold difference (block **3430**). If the difference value **946** is greater than or equal to a threshold difference (block **3430**), the example fault detector **910** increments a fault counter (block **3432**). The fault detector **910** then determines whether the value of the fault counter is greater than or equal to a threshold count (block **3434**).

If the value of the fault counter is greater than or equal to a threshold count (block **3434**), the example fault detector **910** outputs the fault signal **958** (block **3436**). Outputting the fault signal corresponds to the example fault state **1206** of FIG. **12**. The example fault signal **958** may provide an alert to a motor controller (e.g., the motor controller **110** of FIGS. **1** and/or **2**) and/or to an output to alert an operator of the detected winding fault. The fault detector **910** determines whether the fault signal has been reset (block **3438**). For example, the fault detector **910** may receive an input that resets a fault flag and causes the fault detector **910** to return to the transient state **1202**. If the fault signal has not been reset (block **3438**), the example fault detector **910** remains in the fault state **1206** and returns control to block **3438**. If the fault signal has been reset (block **3438**), the example fault detector returns to the transient state **1202** and returns control to block **3302**.

If the difference value **946** is less than the threshold difference (block **3430**), the example fault detector **910** resets the fault counter (block **3440**). After resetting the fault counter (block **3440**), or if the value of the fault counter is

less than the threshold count (block 3434), the example fault detector 910 returns control to block 3416 and remains in the stable state 1204).

FIG. 35A-35E is a flowchart representative of example machine readable instructions 3500 which may be executed by the example fault detection circuits of FIGS. 9 and/or 10 to measure the positive sequence voltage magnitude value 932 (e.g., $|V_p|$), the positive sequence current magnitude value 934 (e.g., $|I_p|$), and the negative sequence voltage values 936a, 936b (e.g., V_{nd} , V_{nq}).

The example instructions 3500 of FIGS. 35A-35E may be used to implement any of blocks 3110, 3130, 3210, 3234, 3304, 3318, 3404, and/or 3418 of FIGS. 31A, 31B, 32A, 32B, 33A, 33B, 34A, and/or 34B. The example instructions 3500 are described below with reference to the fault detection circuit 900 of FIG. 9, the positive sequence voltage magnitude calculator 902 of FIG. 11, the positive sequence current magnitude calculator 904 of FIG. 16, and the negative sequence voltage calculator 906 of FIG. 21. However, the example instructions 3500 may also be executed to implement the fault detection circuit 1000 by using 2 phase PWM measurements instead of 3 phase PWM measurements and using 3 phase current measurements instead of 2 phase current measurements.

The example PWM converter 968 of FIG. 9 obtains 3 phase PWM measurements (e.g., the PWM signals 120a-120c of FIGS. 1 and/or 2) (block 3502).

The PWM converter 968 converts the phase PWM measurements (e.g., the PWM signals 120a-120c) to corresponding phase voltage signals (block 3504). For example, the PWM converter 968 generates the phase voltage signals 920a-920c of FIG. 9.

The example Clarke transformer 928 obtains 2 phase current measurements (e.g., 2 of the 3 phase currents 930a, 930b, 930c of FIG. 9) (block 3506).

The example Clarke transformer 918 performs a Clarke transformation on the phase voltage signals 920a-920c to obtain an alpha voltage signal 916a and a beta voltage signal 916b (block 3508).

The example Park transformer 1102 of FIG. 11 receives the alpha voltage signal 916a and the beta voltage signal 916b and performs a Park transformation on the alpha voltage signal 916a and the beta voltage signal 916b based on the phase angle signal 960 (e.g., generated by and received from the data acquisition controller 912 of FIG. 9) to generate a direct positive sequence voltage signal 1112a and a quadrature positive sequence voltage signal 1112b (block 3510).

The example windower 1104 of FIG. 11 applies window function(s) to the direct positive sequence voltage signal 1112a and the quadrature positive sequence voltage signal 1112b based on a window phase angle signal 962 (e.g., generated by and received from the data acquisition controller 912 of FIG. 9) to generate a windowed direct positive sequence voltage signal 1114a and a windowed quadrature positive sequence voltage signal 1114b (block 3512).

The example integrator 1106 of FIG. 11 adds the windowed direct positive sequence voltage signal 1114a to an integrated direct positive sequence voltage signal 1116a (block 3514). The example integrator 1106 of FIG. 11 also adds the windowed quadrature positive sequence voltage signal 1114b to an integrated quadrature positive sequence voltage magnitude signal 1116b (block 3516).

Turning to FIG. 35B, the example Clarke transformer 928 performs a Clarke transformation on the phase current signals 930a, 930b to obtain an alpha current signal 926a and a beta current signal 926b (block 3518).

The example Park transformer 1602 of FIG. 16 receives the alpha current signal 926a and the beta current signal 926b and performs a Park transformation on the alpha current signal 926a and the beta current signal 926b based on the phase angle signal 960 (e.g., generated by and received from the data acquisition controller 912 of FIG. 9) to generate a direct positive sequence current signal 1612a and a quadrature positive sequence current signal 1612b (block 3520).

The example windower 1604 of FIG. 16 applies window function(s) to the direct positive sequence current signal 1612a and a quadrature positive sequence current signal 1612b based on the window phase angle signal 962 (e.g., generated by and received from the data acquisition controller 912 of FIG. 9) to generate a windowed direct positive sequence current signal 1614a and a windowed quadrature positive sequence current signal 1614b (block 3522).

The example integrator 1606 of FIG. 16 adds the windowed direct positive sequence current signal 1614a to an integrated direct positive sequence current signal 1616a (block 3524). The example integrator 1606 of FIG. 16 also adds the windowed quadrature positive sequence current signal 1614b to an integrated quadrature positive sequence current signal 1616b (block 3526).

Turning to FIG. 35C, the example inverse Park transformer 2102 of FIG. 21 receives the alpha voltage signal 916a and the beta voltage signal 916b and performs an inverse Park transformation on the alpha voltage signal 916a and the beta voltage signal 916b based on the phase angle signal 960 (e.g., generated by and received from the data acquisition controller 912 of FIG. 9) to generate a direct negative sequence voltage signal 2112a and a quadrature negative sequence voltage signal 2112b (block 3528).

The example windower 2104 of FIG. 21 applies window function(s) to the direct negative sequence voltage signal 2112a and the quadrature negative sequence voltage signal 2112b based on a window phase angle signal 962 (e.g., generated by and received from the data acquisition controller 912 of FIG. 9) to generate a windowed direct negative sequence voltage signal 2114a and a windowed quadrature negative sequence voltage signal 2114b (block 3530).

The example integrator 2106 of FIG. 21 adds the windowed direct negative sequence voltage signal 2114a to an integrated direct negative sequence voltage signal 2116a (block 3532). The example integrator 2106 of FIG. 21 also adds the windowed quadrature negative sequence voltage signal 2114b to an integrated quadrature negative sequence voltage signal 2116b (block 3534).

Turning to FIG. 35D, the example positive sequence voltage calculator 902, the example positive sequence current calculator 904, and/or the example negative sequence voltage calculator 906 determine whether the integrator reset signal 964 and/or the latch signal 966 have been received (e.g., from the data acquisition controller 912) (block 3536). If the integrator reset signal 964 and/or the latch signal 966 have not been received (block 3536), the example fault detection circuit 900 returns control to block 3502 to continue collecting samples.

When the integrator reset signal 964 and/or the latch signal 966 have been received (e.g., from the data acquisition controller 912) (block 3536), the example integrator 1106 outputs the integrated direct positive sequence voltage signal 1116a and the integrated quadrature positive sequence voltage signal 1116b to the positive sequence voltage buffer 1108 (block 3538). The example integrator 1106 then resets the integrated direct positive sequence voltage signal 1116a and the integrated quadrature positive sequence voltage

signal **1116b** (block **3540**). The example positive sequence voltage buffer **1108** of FIG. **11** outputs the buffered direct positive sequence voltage signal **1118a** and the buffered quadrature positive sequence voltage signal **1118b** stored in a positive sequence voltage buffer (block **3542**).

The example amplitude calculator **1110** calculates and outputs an amplitude of the buffered direct positive sequence voltage magnitude signal **1118a** and a buffered quadrature positive sequence voltage signal **1118b** as the positive sequence voltage magnitude value **VA 932** (block **3544**).

The example integrator **1606** outputs the integrated direct positive sequence current signal **1616a** and the integrated quadrature positive sequence current signal **1616b** to the positive sequence current buffer **1608** (block **3546**). The example integrator **1606** then resets the integrated direct positive sequence current signal **1616a** and the integrated quadrature positive sequence current signal **1616b** (block **3548**).

The example positive sequence current buffer **1608** of FIG. **16** outputs the buffered direct positive sequence current signal **1618a** and the buffered quadrature positive sequence current signal **1618b** stored in the positive sequence current magnitude buffer **1608** (block **3550**). The example amplitude calculator **1610** calculates and outputs an amplitude of the buffered direct positive sequence current signal **1618a** and a buffered quadrature positive sequence current signal **1618b** as the positive sequence current magnitude value $|I_p|$ **934** (block **3552**).

Turning to FIG. **35E**, the example integrator **2106** outputs the integrated direct negative sequence voltage signal **2116a** and the integrated quadrature negative sequence voltage signal **2116b** to the negative sequence voltage buffer **1608** (block **3554**). The example integrator **2106** then resets the integrated direct negative sequence voltage signal **2116a** and the integrated quadrature negative sequence voltage **2116b** (block **3556**).

The example negative sequence voltage buffer **2108** of FIG. **21** outputs the buffered direct negative sequence voltage signal **2118a** and the buffered quadrature negative sequence voltage signal **2118b** stored in the negative sequence voltage buffer **2108** (block **3558**). The example low pass filter **2110** filters the buffered direct negative sequence voltage signal **2118a** and the buffered quadrature negative sequence voltage signal **2118b** (block **3560**). For example, the low pass filter **2110** may filter the integrated direct phase negative sequence voltage signal **2116a** and the integrated quadrature negative sequence voltage signal **2116b** when the signals **2116a**, **2116b** are obtained at the latch **2108**.

The example fault detection circuit **900** returns control to block **3502** of FIG. **35A** to continue collecting data.

FIG. **36** is a flowchart representative of example machine readable instructions which may be executed to implement the example data acquisition controller of FIGS. **9**, **10**, and **26** to control measurement of the positive sequence voltage magnitude value **932** (e.g., $|V_p|$), the positive sequence current magnitude value **934** (e.g., $|I_p|$), and the negative sequence voltage values **936a**, **936b** (e.g., V_{nd} , V_{nq}).

The example data acquisition controller **2600** of FIG. **26** enters a “wait” state, in which the data acquisition controller **2600** awaits a zero crossing on an input phase voltage signal (e.g., the phase voltage signal **920a** of FIGS. **9**, **10**, and **26**) (block **3602**). When entering the “wait” state, the example sample counter **2604** resets (e.g., to a value of “0”).

The sample counter **2604** determines whether a sampling clock signal **2618** (e.g., a pulse or rising edge on the sampling clock signal **2618**) has been received (block **3604**).

When the sampling clock signal **2618** is received (block **3604**), a sampling clock counter is incremented (block **3606**). By incrementing the sampling clock counter, the example sample counter **2604** measures a number of sampling cycles between zero crossings.

After incrementing the sampling clock counter (block **3606**), or if a sampling clock signal **2618** has not been received (block **3604**), the zero crossing detector **2602** determines whether a zero crossing (e.g., a positive zero crossing) is detected on the phase voltage signal **920a** (block **3608**). For example, the zero crossing detector **2602** may monitor the phase voltage signal **920a** and output a zero crossing signal **2616** in response to identifying a positive zero crossing. If a zero crossing is not detected (block **3608**), control iterates to block **3604** to determine whether the sampling clock signal has been received.

When a zero crossing (e.g., a positive zero crossing) is detected on the phase voltage signal **920a** (block **3608**), the example data acquisition controller **2600** enters a “collect” state and outputs a reset signal **964** and a latch signal **966** to the positive sequence voltage magnitude calculators **902**, the example positive sequence current magnitude calculators **904**, and/or the example negative sequence voltage calculators **906** (block **3610**).

The example angular change calculator **2606** calculates a phase period **2620** of the phase voltage signal **920a** as the time (e.g., in cycles of the sampling clock signal **2618**) between the two most recent zero crossing signals **2616** from the zero crossing detector **2602** (block **3612**). The example window angle calculator **912** calculates a target number of sample cycles over which to integrate based on a period of the phase voltage signal **920a** (e.g., calculated by the angle change calculator **2606** of FIG. **26**) and a target number of samples (block **3614**). In some examples, the sample counter **2604** rounds the calculated number of sample cycles to a nearest power of 2 (e.g., 1, 2, 4, 8, etc.).

The example window angle calculator **2612** sets the sample counter **2604** (block **3616**). For example, the window angle calculator **2612** may set the sample counter **2604** to a product of the calculated target number of sample cycles and the number of cycles counted by the sampling clock counter. The sample counter keeps track of a number of cycles of the sampling clock signal **2618** that have occurred. The example sample counter **2604** then resets the sampling clock counter (block **3618**).

The phase angle calculator **2610** and/or the window angle calculator **2612** determine whether a sampling clock signal **2618** (e.g., a pulse or rising edge on the sampling clock signal **2618**) has been received (block **3620**). If the sampling clock signal **2618** has not been received (block **3620**), the example phase angle calculator **2610** and/or the window angle calculator **2612** return control to block **3620** to await the sampling clock signal **2618**.

When the sampling clock signal **2618** is received (block **3620**), the example phase angle calculator **2610** calculates and outputs a phase angle signal **960** (block **3622**). For example, the phase angle calculator **2610** may increment the phase angle signal **960** by the angular rate of change **2622** when the sampling clock signal **2618** is received. The phase angle calculator **2610** outputs the phase angle signal **960** to the Park transformers **1102**, **1602** of FIGS. **11** and/or **16**, and to the inverse Park transformer **2102** of FIG. **21**.

The window angle calculator **2612** calculates and outputs a window phase angle signal **962** (block **3624**). For example, the window angle calculator **2612** may calculate the an increment value by dividing the angular rate of change **2622** by the calculated target number of cycles, and increment the

window phase angle signal **962** by the increment value in response to the sampling clock signal **2618**.

The example window angle calculator **2612** decrements the sample counter **2604** (block **3626**). The example sample counter **2604** increments the sampling clock counter (block **3628**). The example window angle calculator **2612** determines whether a value of the sample counter is equal to 0 (block **3630**). If the value of the value of the sample counter is equal to 0 (block **3630**), control returns to block **3602** and the data acquisition controller **2600** enters the “wait” state. If the value of the sample counter is not equal to 0 (block **3630**), control returns to block **3620** to await a next sampling clock signal **2618**.

FIG. **37** is a block diagram of an example test apparatus **3700** including the example fault detection circuit **900**, **1000** of FIGS. **9** and/or **10** to test a detection of winding faults in a motor **3702**. The example test apparatus **3700** of FIG. **37** includes a motor driver **3704** implementing the fault detection circuit **900**, a dynamometer **3706**, a dynamometer controller **3708**, and a controller **3710**.

The example motor **3702** is a wye-connected three-phase brushless direct current (DC) electric motor constructed with multiple winding taps shown in the table **3712** of FIG. **37**. These taps represent the number of turns from the neutral point. Besides connecting a tap to neutral, it is possible to connect tap to tap to generate other fault levels. For example, a 3% fault can be created by connecting the 9% to the 2% tap or the 4% tap to the 1% tap. As shown in the table **3712**, the motor **3702** has taps at 1%, 2%, 9%, 15%, and 25% of the windings, relative to the neutral point of the three-phases.

The motor driver **3704** is a Texas Instruments’ DRV12F642 EVM inverter board, which is connected to the controller **3710** (e.g., a personal computer) via a bus **3714** such as a USB cable. The dynamometer **3706** of FIG. **37** is a Magtrol HD-705-6N dynamometer, which is connected to the motor **3702** via a flexible coupling **3716**. A brake port **3718** and an instrumentation port **3720** of the dyno are connected via cables to the dynamometer controller **3708**, which is a Magtrol Model DSP6001 dynamometer controller. The dynamometer controller **3708** is connected to the controller through a general purpose interface bus (GPIB) interface **3722**.

Speed and load robustness testing was conducted through a LabView-based ATE (Automatic Test Equipment) residing on the controller **3710** (a host PC). The controller **3710** recorded data across 3 speeds (500, 1000, and 1500 RPM) and 16 loads (1, 2, 3, 4, 9, 11, and 16 lb-in). Each data point included the positive sequence current magnitude and positive sequence voltage magnitude magnitudes, and the negative sequence voltage components. To accomplish this, the controller **3710** sent speed commands via the ATE through the USB cable **3714** to the motor driver **3704** and torque commands to the dynamometer **3706** controlled via the GPIB interface **3722**. At each load, speed operating point, the controller **3710** would direct the motor driver **3704** to record 11 data points 10 seconds apart. A fault switch **3724** connected to the taps of the motor **3702** enables creation of various faults by connecting one or more of the taps to the neutral reference and/or connecting two or more of the taps together.

FIG. **38** is a graph **3800** of example time periods **3802** required by the example fault detection circuit **900** used in the test apparatus **3700** of FIG. **37** to detect an winding fault in the motor **3702** following simulation of the winding fault in the motor **3702**.

The fault detection time is a product of the electrical cycle time and the number of integration cycles used by the fault detection circuit. The number of integration cycles is increased at higher speeds to ensure that a sufficient number are used in the sequence calculation. The detection time T_d is given by the following Equations 12 and 13:

$$T_s = \frac{60 f_{PWM}}{RPM \cdot n_p} \quad \text{Equation 12}$$

$$T_d = 2 \cdot 2^{\lceil \log_2 \left(\lceil \frac{n_{targ}}{T_s} \rceil \right)} \cdot T_s \quad \text{Equation 13}$$

In Equations 12 and 13, f_{PWM} is the PWM frequency in Hertz, n_p is the motor pole pairs, RPM is the rotations per minute of the motor **3702**, n_{targ} is the target number of samples for integration in the fault detection circuit **900**, and $\lceil \cdot \rceil$ refers to the ceiling operator (e.g., round up to nearest integer). The signal detection time for the fault detection circuit **900** in the test setup shown in FIG. **37** is shown in FIG. **38** as a function of the RPM of the motor **3702**, and varies between 0.25 and 0.50 seconds. The detection time can be adjusted by varying the target number of samples n_{targ} used by the fault detection circuit **900**, at a cost of reduced sensitivity and/or increased false positives.

FIG. **39** illustrates example phase voltages **3902**, **3904**, **3906** of the three-phase motor **3702** before **3908** and after **3910** an example winding fault is created in the example test apparatus **3700** of FIG. **37**. As shown in FIG. **39**, during the period before **3908** the winding fault is invoked at time **3912**, the phase voltages **3902**, **3904**, **3906** are balanced and having nearly identical amplitudes. In the period after **3910** the winding fault is invoked at time **3912**, the phase voltages **3902**, **3904**, **3906** are noticeably unbalanced.

FIG. **40** illustrates example an example positive phase sequence **4002**, an example negative phase sequence **4004**, and an example zero phase sequence **4006** representative of the phase voltages **3902**, **3904**, **3906** of FIG. **39** before, during, and after the simulated winding fault at time **3822** in FIG. **39** in the example test apparatus **3700** of FIG. **37**. As shown in FIG. **40**, at the time **3912** of the winding fault the positive phase sequence **4002** is decreased and the negative phase sequence **4004** is increased due to the winding fault. The example fault detection circuit **900** of FIG. **9** detects the increase in the negative phase sequence **4004** as described herein to detect the winding faults.

FIGS. **41-44** illustrate example negative sequence voltages at various motor speeds and motor loads performed using the test apparatus of FIG. **37**. FIG. **41** illustrates example groups of negative sequence voltages at a motor speed of 500 RPM and a load of 1 lb-in, with no winding faults **4102**, a 1% winding fault **4104**, a 2% winding fault **4106**, a 3% winding fault **4108**, and a 5% winding fault **4110**. As shown in FIG. **41**, the 2% winding fault **4106**, the 3% winding fault **4108**, and the 5% winding fault **4110** are clearly distinguishable from no winding fault **4102**.

FIG. **42** illustrates example groups of negative sequence voltages at a motor speed of 500 RPM and a load of 16 lb-in, with no winding faults **4202**, a 1% winding fault **4204**, a 2% winding fault **4206**, a 3% winding fault **4208**, and a 5% winding fault **4210**. As shown in FIG. **42**, the 1% winding fault **4204**, the 2% winding fault **4206**, the 3% winding fault **4208**, and the 5% winding fault **4210** are clearly distinguishable from no winding fault **4202**.

FIG. **43** illustrates example groups of negative sequence voltages at a motor speed of 1500 RPM and a load of 1 lb-in,

45

with no winding faults **4302**, a 1% winding fault **4304**, a 2% winding fault **4306**, a 3% winding fault **4308**, and a 5% winding fault **4400**. As shown in FIG. **43**, the 1% winding fault **4304**, the 2% winding fault **4306**, the 3% winding fault **4308**, and the 5% winding fault **4310** are clearly distinguishable from no winding fault **4302**.

FIG. **44** illustrates example groups of negative sequence voltages at a motor speed of 1500 RPM and a load of 16 lb-in, with no winding faults **4402**, a 1% winding fault **4404**, a 2% winding fault **4406**, a 3% winding fault **4408**, and a 5% winding fault **4410**. As shown in FIG. **44**, the 1% winding fault **4404**, the 2% winding fault **4406**, the 3% winding fault **4408**, and the 9% winding fault **4410** are clearly distinguishable from no winding fault **4402**.

FIG. **45** is a block diagram of an example processor platform **4500** capable of executing the instructions of FIGS. **31A-31B**, **32A-32B**, **33A-33B**, **34A-34B**, **35A-35E**, and **36** to implement the positive sequence voltage magnitude calculators **902**, the example positive sequence current magnitude calculators **904**, the example negative sequence voltage calculators **906**, the example interpolator **908**, the example fault detector **910**, the example data acquisition controllers **912**, **2600**, the example learner **914**, the example Clarke transformers **918**, **928**, the example baseline table **940**, the example storage device **942**, the example subtractors **944a**, **944b**, the example amplitude calculators **948**, **1110**, **1610**, the example high pass filter **952**, the example Park transformers **1102**, **1602**, the example windowers **1104**, **1604**, **2104**, the example integrators **1106**, **1606**, **2106**, the example positive sequence voltage magnitude buffer **1108**, the example positive sequence current magnitude buffer **1608**, the example negative sequence voltage buffer **2108**, the example low pass filter **2110**, the example zero crossing detector **2602**, the example angular change calculator **2606**, the example sample counter **2604**, the example sampling clock **2608**, the example phase angle calculator **2610**, the example window angle calculator **2612**, and/or the example reset trigger **2614** of FIGS. **9**, **11**, **16**, **21**, and **26**. The processor platform **4500** can be, for example, a server, a personal computer, or any other type of computing device.

The processor platform **4500** of the illustrated example includes a processor **4512**. The processor **4512** of the illustrated example is hardware. For example, the processor **4512** can be implemented by one or more integrated circuits, logic circuits, microprocessors or controllers from any desired family or manufacturer. The example processor platform **4500** may implement the example positive sequence voltage magnitude calculators **902**, the example positive sequence current magnitude calculators **904**, the example negative sequence voltage calculators **906**, the example interpolator **908**, the example fault detector **910**, the example data acquisition controllers **912**, **2600**, the example learner **914**, the example Clarke transformers **918**, **928**, the example subtractors **944a**, **944b**, the example amplitude calculators **948**, **1110**, **1610**, the example high pass filter **952**, the example Park transformers **1102**, **1602**, the example windowers **1104**, **1604**, **2104**, the example integrators **1106**, **1606**, **2106**, the example positive sequence voltage magnitude buffer **1108**, the example positive sequence current magnitude buffer **1608**, the example negative sequence voltage buffer **2108**, the example low pass filter **2110**, the example zero crossing detector **2602**, the example angular change calculator **2606**, the example sample counter **2604**, the example sampling clock **2608**, the example phase angle calculator **2610**, the example window angle calculator **2612**, and/or the example reset trigger **2614**

46

The processor **4512** of the illustrated example includes a local memory **4513** (e.g., a cache). The processor **4512** of the illustrated example is in communication with a main memory including a volatile memory **4514** and a non-volatile memory **4516** via a bus **4518**. The volatile memory **4514** may be implemented by Synchronous Dynamic Random Access Memory (SDRAM), Dynamic Random Access Memory (DRAM), RAMBUS Dynamic Random Access Memory (RDRAM) and/or any other type of random access memory device. The non-volatile memory **4516** may be implemented by flash memory and/or any other desired type of memory device. Access to the main memory **4514**, **4516** is controlled by a memory controller.

The processor platform **4500** of the illustrated example also includes an interface circuit **4520**. The interface circuit **4520** may be implemented by any type of interface standard, such as an Ethernet interface, a universal serial bus (USB), and/or a PCI express interface.

In the illustrated example, one or more input devices **4522** are connected to the interface circuit **4520**. The input device(s) **4522** permit(s) a user to enter data and commands into the processor **4512**. The input device(s) can be implemented by, for example, an audio sensor, a microphone, a camera (still or video), a keyboard, a button, a mouse, a touchscreen, a track-pad, a trackball, isopoint and/or a voice recognition system.

One or more output devices **4524** are also connected to the interface circuit **4520** of the illustrated example. The output devices **4524** can be implemented, for example, by display devices (e.g., a light emitting diode (LED), an organic light emitting diode (OLED), a liquid crystal display, a cathode ray tube display (CRT), a touchscreen, a tactile output device, a light emitting diode (LED), a printer and/or speakers). The interface circuit **4520** of the illustrated example, thus, typically includes a graphics driver card, a graphics driver chip or a graphics driver processor.

The interface circuit **4520** of the illustrated example also includes a communication device such as a transmitter, a receiver, a transceiver, a modem and/or network interface card to facilitate exchange of data with external machines (e.g., computing devices of any kind) via a network **4526** (e.g., an Ethernet connection, a digital subscriber line (DSL), a telephone line, coaxial cable, a cellular telephone system, etc.).

The processor platform **4500** of the illustrated example also includes one or more mass storage devices **4528** for storing software and/or data. Examples of such mass storage devices **4528** include floppy disk drives, hard drive disks, compact disk drives, Blu-ray disk drives, RAID systems, and digital versatile disk (DVD) drives. The example mass storage devices **4528** of FIG. **45** may implement the example baseline table **940** and/or the example storage device **942**.

The coded instructions **4532** of FIGS. **31A-31B**, **32A-32B**, **33A-33B**, **34A-34B**, **35A-35E**, and **36** may be stored in the mass storage device **4528**, in the volatile memory **4514**, in the non-volatile memory **4516**, and/or on a removable tangible computer readable storage medium such as a CD or DVD.

FIG. **46** is a block diagram of an example processor platform **4600** capable of executing the instructions of FIGS. **31A-31B**, **32A-32B**, **33A-33B**, **34A-34B**, **35A-35E**, and **36** to implement the positive sequence voltage magnitude calculators **902**, the example positive sequence current magnitude calculators **904**, the example negative sequence voltage calculators **906**, the example interpolator **908**, the example fault detector **910**, the example data acquisition controllers **912**, **2600**, the example learner **914**, the example Clarke

transformers **918**, **928**, the example baseline table **940**, the example storage device **942**, the example subtractors **944a**, **944b**, the example amplitude calculators **948**, **1110**, **1610**, the example high pass filter **952**, the example Park transformers **1102**, **1602**, the example windowers **1104**, **1604**, **2104**, the example integrators **1106**, **1606**, **2106**, the example positive sequence voltage buffer **1108**, the example positive sequence current buffer **1608**, the example negative sequence voltage buffer **2108**, the example low pass filter **2110**, the example zero crossing detector **2602**, the example angular change calculator **2606**, the example sample counter **2604**, the example sampling clock **2608**, the example phase angle calculator **2610**, the example window angle calculator **2612**, and/or the example reset trigger **2614** of FIGS. **10**, **11**, **16**, **21**, and **26**. The processor platform **4600** can be, for example, a server, a personal computer, or any other type of computing device.

The processor platform **4600** of the illustrated example includes a processor **4612**. The processor **4612** of the illustrated example is hardware. For example, the processor **4612** can be implemented by one or more integrated circuits, logic circuits, microprocessors or controllers from any desired family or manufacturer.

The processor **4612** of the illustrated example includes a local memory **4613** (e.g., a cache). The processor **4612** of the illustrated example is in communication with a main memory including a volatile memory **4614** and a non-volatile memory **4616** via a bus **4618**. The volatile memory **4614** may be implemented by Synchronous Dynamic Random Access Memory (SDRAM), Dynamic Random Access Memory (DRAM), RAMBUS Dynamic Random Access Memory (RDRAM) and/or any other type of random access memory device. The non-volatile memory **4616** may be implemented by flash memory and/or any other desired type of memory device. Access to the main memory **4614**, **4616** is controlled by a memory controller.

The processor platform **4600** of the illustrated example also includes an interface circuit **4620**. The interface circuit **4620** may be implemented by any type of interface standard, such as an Ethernet interface, a universal serial bus (USB), and/or a PCI express interface.

In the illustrated example, one or more input devices **4622** are connected to the interface circuit **4620**. The input device(s) **4622** permit(s) a user to enter data and commands into the processor **4612**. The input device(s) can be implemented by, for example, an audio sensor, a microphone, a camera (still or video), a keyboard, a button, a mouse, a touchscreen, a track-pad, a trackball, isopoint and/or a voice recognition system.

One or more output devices **4624** are also connected to the interface circuit **4620** of the illustrated example. The output devices **4624** can be implemented, for example, by display devices (e.g., a light emitting diode (LED), an organic light emitting diode (OLED), a liquid crystal display, a cathode ray tube display (CRT), a touchscreen, a tactile output device, a light emitting diode (LED), a printer and/or speakers). The interface circuit **4620** of the illustrated example, thus, typically includes a graphics driver card, a graphics driver chip or a graphics driver processor.

The interface circuit **4620** of the illustrated example also includes a communication device such as a transmitter, a receiver, a transceiver, a modem and/or network interface card to facilitate exchange of data with external machines (e.g., computing devices of any kind) via a network **4626** (e.g., an Ethernet connection, a digital subscriber line (DSL), a telephone line, coaxial cable, a cellular telephone system, etc.).

The processor platform **4600** of the illustrated example also includes one or more mass storage devices **4628** for storing software and/or data. Examples of such mass storage devices **4628** include floppy disk drives, hard drive disks, compact disk drives, Blu-ray disk drives, RAID systems, and digital versatile disk (DVD) drives. The example mass storage devices **4628** of FIG. **46** may implement the example baseline table **940** and/or the example storage device **942**.

The coded instructions **4632** of FIGS. **31A-31B**, **32A-32B**, **33A-33B**, **34A-34B**, **35A-35E**, and **36** may be stored in the mass storage device **4628**, in the volatile memory **4614**, in the non-volatile memory **4616**, and/or on a removable tangible computer readable storage medium such as a CD or DVD.

Modifications are possible in the described embodiments, and other embodiments are possible, within the scope of the claims.

What is claimed is:

1. A motor winding fault detection circuit, comprising:
 - a first Clarke transformer to output an alpha voltage signal and a beta voltage signal, responsive to multi-phase voltage signals;
 - a second Clarke transformer to output an alpha current signal and a beta current signal, responsive to multi-phase current signals;
 - a positive sequence voltage calculator to calculate a positive sequence voltage value for a three-phase motor, responsive to the alpha voltage signal and the beta voltage signal;
 - a positive sequence current calculator to calculate a positive sequence current value for the three-phase motor, responsive to the alpha current signal and the beta current signal;
 - an interpolator to calculate an expected negative sequence voltage value, responsive to the positive sequence voltage value, the positive sequence current value, and measured characteristics of the three-phase motor;
 - a negative sequence voltage calculator to calculate a measured negative sequence voltage value for the three-phase motor, responsive to the alpha voltage signal and the beta voltage signal; and
 - a fault detector to detect that a winding fault exists in the three-phase motor when a difference between the expected negative sequence voltage value and the measured negative sequence voltage value satisfies a threshold.
2. The fault detection circuit of claim 1, further including a learner to store training negative sequence voltage values corresponding to combinations of training positive sequence voltage values and training positive sequence current values, the interpolator to calculate the expected negative sequence voltage value responsive to the training negative sequence voltage values, the training positive sequence voltage values, and the training positive sequence current values.
3. The fault detection circuit of in claim 2, wherein the interpolator is to calculate the expected negative sequence voltage value by:
 - identifying one of the combinations of the training positive sequence voltage values and the training positive sequence current values responsive to the positive sequence voltage value and the positive sequence current value; and
 - interpolating the expected negative sequence voltage value using one of the training negative sequence voltage values that corresponds to the identified one of

49

the one of the combinations of the training positive sequence voltage values and the training positive sequence current values.

4. The fault detection circuit of claim 2, wherein the interpolator is to calculate the expected negative sequence voltage value by:

identifying three or more of the combinations of the training positive sequence voltage values and the training positive sequence current values responsive to the positive sequence voltage value and the positive sequence current value of the combinations of the training positive sequence voltage values and the training positive sequence current values; and

interpolating the expected negative sequence voltage value using three or more of the training negative sequence voltage values that correspond to the identified three or more of the combinations of the training positive sequence voltage values and the training positive sequence current values.

5. The fault detection circuit of claim 2, wherein the learner is to store the training negative sequence voltage values only while first measured changes in the training positive sequence voltage values are less than a first threshold and second measured changes in the training positive sequence current values are less than a second threshold.

6. The fault detection circuit of claim 5, wherein the learner is to enter a transient state when the first measured changes in the training positive sequence voltage values are greater than the first threshold or when the second measured changes in the training positive sequence current values are greater than the second threshold, and is to not store training negative sequence voltage values while in the transient state.

7. The fault detection circuit of claim 1, wherein the fault detector is to: enter a transient state when first measured changes in a set of positive sequence voltage values are greater than a first threshold or when second measured changes in a set of positive sequence current values are greater than a second threshold; detect that the winding fault exists only while the first measured changes in the set of positive sequence voltage values are less than the first threshold and the second measured changes in the set of positive sequence current values are less than the second threshold; and not detect whether winding faults exist while in the transient state.

8. The fault detection circuit of claim 1, further including a learner to calculate a relationship between negative sequence voltage values, training positive sequence voltage values, and training positive sequence current values, the detection that the winding fault exists being based on the relationship.

9. The fault detection circuit of claim 8, wherein the interpolator is to calculate the expected negative sequence voltage value using the relationship, the positive sequence voltage value, and the positive sequence current value.

10. The fault detection circuit of claim 1, further including a data acquisition controller to control the positive sequence voltage calculator, the positive sequence current calculator, and the negative sequence voltage calculator.

11. The fault detection circuit of claim 10, wherein the data acquisition controller is to control a number of samples of a phase voltage used by the positive sequence voltage calculator to the positive sequence voltage value.

12. The fault detection circuit of claim 1, further including a pulse width modulation converter to receive a pulse width modulation signal and to generate a phase voltage responsive to the pulse width modulation signal, the positive

50

sequence voltage calculator to use the phase voltage to calculate the positive sequence voltage value.

13. The fault detection circuit of claim 1, wherein the expected negative sequence voltage value is an expected quadrature negative sequence voltage value.

14. The fault detection circuit of claim 1, wherein the measured negative sequence voltage value is a measured quadrature negative sequence voltage value.

15. The fault detection circuit of claim 1, wherein the expected negative sequence voltage value is an expected quadrature negative sequence voltage value, and the measured negative sequence voltage value is a measured quadrature negative sequence voltage value.

16. The fault detection circuit of claim 1, wherein the measured characteristics of the three-phase motor are training data stored in a baseline table.

17. A fault detection circuit, comprising:

a first Clarke transformer having multi-phase voltage signals as a first input and having an alpha voltage signal as a first output and a beta voltage signal as a second output;

a positive sequence voltage calculator having the alpha voltage signal as a second input and the beta voltage signal as a third input, and having a positive sequence voltage value as a third output;

a negative sequence voltage calculator having the alpha voltage signal as a fourth input and the beta voltage signal as a fifth input, and having a direct negative sequence voltage value as a fourth output and a quadrature negative sequence voltage value as a fifth output;

a second Clarke transformer having multi-phase current signals as a sixth input and having an alpha current signal as a sixth output and a beta current signal as a seventh output;

a positive sequence current calculator having the alpha current signal as a seventh input and the beta current signal as an eighth input, and having a positive sequence current value as an eighth output;

an interpolator having the positive sequence voltage value as a ninth input, the positive sequence current value as a tenth input, and a baseline table as an eleventh input, the interpolator to generate, based on training data stored in the baseline table, the positive sequence voltage value, and the positive sequence current value, an expected direct negative sequence voltage value as a ninth output and an expected quadrature negative sequence voltage value as a tenth output;

a first subtractor having the direct negative sequence voltage value as a twelfth input and the expected direct negative sequence voltage value as a thirteenth input, the first subtractor to determine a first difference value between the direct negative sequence voltage value and the expected direct negative sequence voltage value as an eleventh output;

a second subtractor having the quadrature negative sequence voltage value as a fourteenth input and the expected quadrature negative sequence voltage value as a fifteenth input, the second subtractor to determine a second difference value between the quadrature negative sequence voltage value and the expected quadrature negative sequence voltage value as an twelfth output;

an amplitude calculator having the first difference value as a sixteenth input and the second difference value as a seventeenth input, the amplitude calculator to output an amplitude of the first difference value and the second difference value as a thirteenth output; and

a fault detector having the amplitude as a eighteenth input
and to output a fault detection signal as a fourteenth
output when the amplitude satisfies a threshold.
