(57) **ABSTRACT**

Systems and apparatuses for electromagnetic communications are provided. One of the apparatuses includes a housing portion for an electronic device, wherein the housing portion comprises: a first region formed from a first material; and a second region comprising an arrangement of structures formed from the first material and a second material, wherein the arrangement of structures reduce propagation of electromagnetic radiation propagating through the second region.

**STRUCTURES FOR CROSS-TALK  
REDUCTION****BACKGROUND**

This specification relates to electromagnetic communications. Advances in semiconductor manufacturing and circuit design technologies have enabled the development and production of integrated circuits (ICs) with increasingly higher operational frequencies. In turn, electronic products and systems incorporating high frequency integrated circuits are able to provide greater functionality than previous generations of products. The additional functionality has typically included the processing of increasingly larger amounts of data at increasingly higher speeds.

Many conventional electronic systems include multiple printed circuit boards (PCBs) upon which ICs are mounted, and through which various signals are routed to and from the ICs. Connecting to PCBs by conventional means, e.g., signal-carrying mechanical connectors, generally creates discontinuities, requiring expensive electronics to negotiate. Conventional mechanical connectors may also wear out over time, require precise alignment and manufacturing methods, and are susceptible to mechanical jostling.

Communication channels can be formed between one or more transmitter integrated circuit package of one device and one or more corresponding receiver integrated circuit package of another device. Communication signals of a particular communication channel intended for a particular receiver integrated circuit can leak to one or more other communication channels, resulting in cross-talk interference.

**SUMMARY**

The devices and methods disclosed herein allow for reduced cross-talk between communication channels. A communication channel can be formed between a transmitter integrated circuit package of one device and a receiver integrated circuit package of another device. Transmitter integrated circuit packages and receiver integrated circuit packages can also be referred to as connectors. Cross-talk can occur internally within a single device when signals intended for transmission outside the device is received by the receiver of the device.

The devices and methods disclosed herein can reduce a material volume of the devices compared to systems that use distance or absorber structures to isolate the devices and/or individual communication channels. A wide range of materials can be selected to be incorporated into the devices to reduce cross-talk, allowing flexible implementation of the methods and devices disclosed herein, simplifying their fabrication. Some examples of materials that can be chosen include plastics, zirconia, and other insulating materials. For example, structures can be implanted within housing/cases of devices.

In general, one innovative aspect of the subject matter described in this specification can be embodied in apparatuses that include a housing portion for an electronic device, wherein the housing portion includes: a first region formed from a first material; and a second region including an arrangement of structures formed from the first material and a second material, wherein the arrangement of structures reduce propagation of electromagnetic radiation propagating through the second region.

The foregoing and other embodiments can each optionally include one or more of the following features, alone or in

## 2

combination. In particular, one embodiment includes all the following features in combination. The arrangement of structures includes a periodic arrangement of the first material and the second material. The housing portion of the housing including the arrangement of structures has a planar exterior surface. The housing portion is configured to be placed over a first connector, the first region is vertically above the first connector, the first connector is configured to transmit electromagnetic radiation through the first region, and the arrangement of the structures comprises multiple concentric circles surrounding the first region. The housing portion is configured to be placed over multiple connectors, the multiple connectors are configured to transmit electromagnetic radiation through the first portion, and the arrangement of the structures is disposed in regions of the housing portion that are above gaps between the multiple connectors. Multiple holes, slots, or trenches are defined in the first material of the top portion of the housing, and the second material fills the multiple holes to form the arrangement of structures. Multiple slots are defined in the first material, the top portion has a first width and a first length, and the multiple slots extend across the width of the housing portion. A width of the slot filled with the second material is a quarter of a wavelength of the electromagnetic radiation in the second material, and a dimension of a distance between slots in the multiple slots is a quarter of a wavelength of the electromagnetic radiation in the first material. The arrangement of structures is configured to filter electromagnetic radiation having a wavelength between 50 GHz to 70 GHz. A bandwidth of the filter is less than 60%. Multiple holes, slots, or trenches filled with the second material are formed integrally with the housing portion by injection molding. The first material includes plastic and the second material includes foam. The electromagnetic radiation is between 50 to 70 GHz and the arrangement of structures reduces a transmission between a first end of the second region and a second end of the second region by more than 40% over a bandwidth of 5 GHz. The arrangement of structures formed from the first material and the second material includes multiple structures having one or more different shapes and/or one or more different distances between the multiple structures. The arrangement of the structures includes multiple structures having different heights. The arrangement of structures includes structures that have heights smaller than a thickness of the housing.

In general, one innovative aspect of the subject matter described in this specification can be embodied in communications modules that include a transmitter integrated circuit package, a receiver integrated circuit package; a housing enclosing the transmitter integrated circuit package and the receiver integrated circuit package, wherein the housing includes a first material that permits electromagnetic radiation to be transmitted from the transmitter integrated circuit package enclosed by the housing through the housing; and multiple structures formed of a second material different from the first material defined in a region of the housing configured to reduce propagation of electromagnetic signals within the housing, wherein the structures are positioned in the region such that a propagation path through the housing of an electromagnetic signal from the transmitter integrated circuit package to the receiver integrated circuit package crosses one or more of the multiple structures.

The foregoing and other embodiments can each optionally include one or more of the following features, alone or in combination. The communication module further includes an absorber structure, and a printed circuit board on which the transmitter integrated circuit package and the receiver

integrated circuit package are mounted, wherein the multiple structures formed of the second material are configured to reduce cross-talk between the transmitter integrated circuit package and the receiver integrated circuit package. The communication module is configured to establish a communication channel when a second communication module is placed in proximity to the communication module, and wherein the communication channel is between a transmitter integrated circuit package of the second communication module and the receiver integrated circuit package of the communication module, or between a receiver integrated circuit package of the second communication module and the transmitter integrated circuit package of the communication module. The multiple structures formed of a second material include a periodic arrangement of the first material and the second material. Multiple holes, slots, or trenches are defined in the first material of the housing, and the second material fills the multiple holes to form the arrangement of structures. The housing including the multiple structures has a planar exterior surface. Multiple slots are defined in a portion of the housing, the housing having a first width and a first length, and the multiple slots extend across the width of the housing. A width of the slot filled with the second material is a quarter of a wavelength of the electromagnetic radiation in the second material, and a dimension of a distance between slots in the multiple slots is a quarter of a wavelength of the electromagnetic radiation in the first material. The multiple structures are configured to filter electromagnetic radiation having a wavelength between 50 GHz to 70 GHz.

The details of one or more embodiments of the invention are set forth in the accompanying drawings and the description below. Other features, objects, and advantages of the invention will be apparent from the description and drawings, and from the claims.

#### BRIEF DESCRIPTION OF DRAWINGS

FIG. 1 is an overhead view of an example IC package.

FIG. 2 shows a side view representation of an example communication device including an IC package.

#### DETAILED DESCRIPTION

This specification describes electromagnetic (EM) blocking structures for contactless communication. In particular, this specification describes the use of signal blocking structures that introduce discontinuities to reduce cross-talk between communication channels.

Contactless communication may be used to provide signal communications between components on a device or may provide communication between devices. In one example, tightly-coupled transmitter/receiver pairs may be deployed with a transmitter disposed at a terminal portion of a first conduction path and a receiver disposed at a terminal portion of a second conduction path. The transmitter and receiver may be disposed in close proximity to each other depending on the strength of the transmitted energy, and the first conduction path and the second conduction path may not be contiguous with respect to each other. In some examples, the transmitter and receiver may be disposed on separate circuit carriers positioned with the antennas of the transmitter/receiver pair in close proximity. This specification describes a number of different structures that can be employed to reduce or block stray signals leaking from a transmitter associated with a first communication channel to a receiver of another communication channel.

##### Contactless Communication

A transmitter and/or receiver may be configured as an integrated circuit (IC) package, in which one or more antennas may be positioned adjacent to a die and held in place by a dielectric or insulating encapsulation or bond material. An antenna may also be held in place by a lead frame substrate. Examples of antennas embedded in IC packages are shown in the drawings and described below. Note that IC packages may also be referred to as simply packages, and are examples of contactless communication units that are also variously referred to as communication units, communication devices, comm-link chips, comm-link chip assemblies, comm-link chip packages, and/or comm-link packages, which may be configured in various ways.

## 5

For example, IC packages, communication units, communication devices, comm-link chips, comm-link chip assemblies, comm-link chip packages, and/or comm-link packages may each include one or more ICs, chips, or dies and have circuit functionality appropriate for particular applications.

FIG. 1 shows an example IC package 100. The IC package 100 includes a die 102 and a transducer 104 providing conversion between electrical and electromagnetic (EM) signals. The IC package 100 may include additional structures, for example, conductive connectors, such as bond wires, electrically connecting the transducer to bond pads connected to a transmitter or receiver circuit included in die 102. The IC package 100 further includes an encapsulating material 106 formed around at least a portion of the die 102 and/or the transducer 104. In the example IC package 100, the encapsulating material 104 completely covers the die 100 and the transducer 104.

The die 102 includes any suitable structure configured as a circuit on a suitable die substrate. In some implementations, the die can alternatively be referred to as a chip or an integrated circuit. The die substrate may be composed of any suitable semiconductor material, for example, silicon. In some implementations, the die 102 has a length and a width dimension each of substantially 1.0 mm to about 2.0 mm. The die 102 may be mounted with electrical conductors, such as a lead frame, not shown in FIG. 1, electrically coupling the die 102 to one or more external circuits. The IC package 100 can further include a transformer to provide impedance matching between a circuit on the die 102 and the transducer 104.

The transducer 104 may be in the form of a folded dipole, patch antenna, bow tie antenna, loop antenna, or other types of antennas, and is configured to transmit and/or receive electromagnetic signals. In some implementations, the antenna is configured to operate at radio frequencies including radio frequencies in the extremely high frequency (EHF) band of the electromagnetic spectrum, e.g., frequencies from 30 to 300 gigahertz. As shown in IC package 100, the antenna is separate from the die 102, but is coupled to the die 102 by suitable conductors, not shown.

The dimensions of the antenna are determined such that they are suitable for operation in the specified frequency band of the electromagnetic spectrum, e.g., the EHF band.

In one example, a loop configuration of the antenna can be configured to include a substantially 0.1 mm band of material, laid out in a loop substantially 1.4 mm long and substantially 0.53 mm wide, with a gap of substantially 0.1 mm at the mouth of the loop, and with the edge of the loop approximately 0.2 mm from the edge of die 102.

The encapsulating material 106 can be used to assist in holding the various components of IC package 100 in fixed relative positions. The encapsulating material 106 may be formed from a suitable material configured to provide electrical insulation and physical protection for the components of IC package 100. Additionally, the encapsulating material 106 can be selected from a material that does not impede, or that optimizes passage of, signals to or from the transducer 104. For example, the encapsulating material 106 can be composed of glass, plastic, or ceramic. The encapsulating material 106 may also be formed in any suitable shape. For example, the encapsulating material 106 may be in the form of a rectangular block, encapsulating all components of the IC package 100 except for any unconnected ends of conductors connecting the die 102 to external circuits.

FIG. 2 shows a side view representation of an example communication device 200 including an IC package 202 mounted to a PCB 204. The IC package 202 includes a die

## 6

206, a ground plane 208, an antenna 210, and one or more bond wires 212 connecting the die 206 to the antenna 210. The die 206 and antenna 210 are mounted on a package substrate 214 and encapsulated in an encapsulating material. The ground plane 208 is within the package substrate 214 and is a suitable structure configured to provide an electrical ground for the antenna 210. The ground plane 208 can extend the entire length of the package substrate 214 or just a portion, in particular, a portion underneath the antenna 210. The PCB 204 includes a top dielectric layer 216 having a surface 218. The IC package 202 is mounted to the surface 218 with mounting bumps 220 attached to a metallization pattern (not shown).

The PCB 204 also optionally includes a layer 222 spaced from dielectric layer 216 made of conductive material forming a ground plane within the PCB 204. The PCB ground plane may be any suitable structure configured to provide an electrical ground to circuits and components on the PCB 204.

FIG. 3 is a side view of an example communication module 300 including a signal guiding structure. As shown in FIG. 3, the communication module 300 includes a PCB 302, an IC package 304, and a signal guiding structure 306 providing a signal pathway. The communication module 300, can include a transmitter or receiver for transmitting or receiving signals, e.g., radio frequency signals.

In particular, the IC package 304 can correspond to the IC packages described above with respect to FIGS. 1 and 2. The IC package 304 is mounted on the PCB 302. For example, the IC package 304 can be mounted to the PCB as described with respect to FIG. 2.

The communication module 300 can be configured to transmit or receive data using radio frequency communication. For example, if the communication module 300 includes a transmitter, the communication module 300 can transmit data, which can then be received by a receiver, e.g., of another communication module.

The signal guiding structure 306 is configured to aid in directing radio frequency (RF) signals as well as to reduce interference from signals. The signal guiding structure 306 can surround a perimeter of the IC package and extend in the direction of signal transmission and/or reception by a specified amount to provide a channel for emitted or received RF signals. For example, the signal guiding structure 306 can have a height 310 suitable for a particular device including the communication module 300 and that allows the signal guiding structure 306 to be positioned in proximity to a corresponding signal guiding structure of another communication module when used to communicate with another device. The signal guiding structure can be composed of a suitable material that is configured to reduce extraneous signals without disrupting passage of communications along the channel formed by the signal guiding structure 306.

FIG. 3 illustrates one IC package 304 mounted to the PCB 302. However, in other implementations, more than one IC package can be mounted to the same PCB 302.

The communication module 300 can be part of a communication system of a device, e.g., a computer, mobile phone, tablet, kiosk, or other device/system. The communication system can be configured to provide contactless communication using one or more IC packages. For example, the communication system can include two IC packages, one configured as a transmitter and the other configured as a receiver. The communication system can be in communication with a storage device. Thus, for example, the communication system can transfer data between the

data storage unit and an external device using contactless communication provided by the IC packages.

FIG. 4 is a side view diagram 400 illustrating an example of communication between a transmitter and a receiver. For example, a user of a first device may wish to exchange data with a second device. The two devices can be positioned in proximity to each other such that the respective communication modules for transmitting and receiving data are aligned and in range of each other. In particular, for EHF frequencies, the transmitter and receiver of the two devices may need to be within specified distances. The distances can vary, for example, depending on the particular frequencies used, the materials between the transmitter and receiver, and the strength of the transmission.

In FIG. 4, a first device includes a first communication module having a transmitter IC package 402 positioned on a first PCB 404. The transmitter IC package 402 is surrounded by a first signal guiding structure 406 forming a channel. The first signal guiding structure 406 extends to a surface of a first housing 408 of the first device. For example, the first device can be a first mobile phone and the first housing 408 can correspond to the outer case of the first mobile phone.

A second device includes a second communication module having a receiver IC package 410 positioned on a second PCB 412. The receiver IC package 410 is surrounded by a second signal guiding structure 414 forming a channel. The second signal guiding structure 414 extends to a surface of a second housing 416 of the second device. For example, the second device can be a second mobile phone and the second housing 416 can correspond to the outer case of the second mobile phone.

As illustrated by diagram 400, the first signal guiding structure 406 and the second signal guiding structure 414 are aligned and an outer surface of the first housing 408 and the second housing 416 are in physical contact to provide optimal communication distance and interference.

A data transmission from the transmitter IC package 402 passes through the channel formed by the first signal guiding structure 406 and the second signal guiding structure 414 to the receiver IC package 410. For example, a pair of devices can communicate data between each other by transmitting data from the transmitter IC package 402 to the receiver IC package 410. The signal guiding structures along with a proper alignment can maximize the power of the transmission that is received by the receiver IC package. In some implementations, the signal guiding structures can be formed from, or include a layer of, a metallic material that reflects the transmitted data along the signal guiding structures toward the receiver. In some other implementations, the signal guiding structures can be formed from, or include a layer of, an electromagnetic absorbing material to reduce stray signals that may cause interference.

Although transmitted signals from a transmitter are intended for receipt by a particular receiver, cross talk caused by leaking of signal to another channel can result in unintended coupling that interferes with communication on that other channel. Example sources of cross-talk are illustrated in FIGS. 5A and 6.

#### Sources of Cross-Talk

FIG. 5A shows a side view diagram 500 illustrating an example of communication between a pair of communication modules. Diagram 500 includes a portion of a first device 502 and a second device 504.

The first device 502 includes a first communication module 501. The first communication module 501 includes a first transmitter IC package 506 and a first receiver IC package

508 mounted to a first PCB 510. In the example shown, each of the first transmitter IC package 506 and the first receiver IC package 508 is encircled by a respective first signal guiding structure 512, 513. The first signal guiding structures 512, 513 each form a channel extending from the respective IC package to a surface of a first housing 514 of the first device 502. For example, the first device 502 can be a first mobile phone and the first housing 514 can correspond to the outer case of the first mobile phone. Alternatively, the first device 502 can be a docking station and the first housing 514 can be the outer housing of the docking station.

As described above, the signal guiding structures can maximize the power of the transmission that is received by the receiver IC package as well as reduce signal leakage. In some alternative implementations, the distance between the IC package and the housing surface is small and a fully encircling signal guiding structure may be unnecessary. Instead, for example, an absorber structure can be positioned between the transmitter and receiver IC packages.

The second device 504 includes a second communication module 503. The second communication module 503 includes a second transmitter IC package 516 and a second receiver IC package 518 mounted to a second PCB 520. Each of the second transmitter IC package 516 and the second receiver IC package 518 is encircled by a respective second signal guiding structure 522, 523. The second signal guiding structures 522, 523 each provide a channel extending from the respective IC package to a surface of a second housing 524 of the second device 502. For example, the second device 502 can be a second mobile phone and the second housing 524 can correspond to the outer case of the second mobile phone. The second device 504 can be a laptop and the second housing 524 can be the outer case of the laptop.

As shown in FIG. 5A, the first signal guiding structures 512, 513 and the second signal guiding structures 522, 523 are substantially aligned on either side of the respective first and second housings 514, 524. The alignment can assist in decreasing loss from a data transmission 526 from the first transmitter IC package 506 to the second receiver IC package 518 and a data transmission 528 from the second transmitter IC package 516 to the first receiver IC package 508.

As described above, each signal guiding structure is configured to aid in directing radio frequency (RF) signals as well as to reduce interference from signals. The signal guiding structure can at least partially surround a perimeter of the IC package and extend in the direction of signal transmission and/or reception by a specified "height" amount to provide a channel for emitted or received RF signals. The signal guiding structure can be composed of a suitable material that is configured to reduce extraneous signals without disrupting passage of communications along the channel formed by the signal guiding structure. The guiding structure may be in part dielectric, conductive and/or absorbing material. Lensing type structures can be built as part of an interior surface of the case. Even with the signal guiding structures, the potential for unintended coupling between channels can occur. Unintended coupling can occur when signals transmitted by a transmitter IC package are received by unintended receivers. Due to the nature of the electromagnetic field generated by the transmitted signals, particularly at certain frequencies, some signals emitted from the first transmitter IC package 506 and intended for the second receiver IC package 518 can propagate to an adjacent channel, for example, the first receiver IC package 508.

Transmitter IC package and receiver IC package pairs form contactless connectors between the first device **502** and the second device **504**. The contactless connectors are covered by the device housing (i.e., first housing **514** and second housing **524**). The device housing can be device cases that are made of plastic.

For example, as shown in FIG. **5A**, the signal guiding structures **512** and **513** extend to the housing **514** of the first device **502**. The respective housings have a thickness that results in a gap having a thickness that is the sum of the thicknesses of the first housing and the second housing between the corresponding signal guiding structures along the transmission path. Additionally, the housing may be formed of a material that facilitates propagation of EM signals, e.g., a dielectric material. In addition, the dielectric material of the housing can serve as a waveguide for the signal. As a result, signals can propagate through the first housing **514** and/or the second housing **524**, bypassing the signal guiding structures **512**, **513**, as illustrated by dashed line **530**. The signals can then be received by the first receiver IC package **508**. This can lead to parasitic signals caused by interference, which are also known as cross-talk between connector lanes. One connector lane can be, for example, the transmission of signal **526** from the transmitter IC package **506** of the first device **502** to receiver IC package **518** of the second device **504**. A second connector lane can be, for example, the transmission of signal **528** from the transmitter IC package **516** of the second device **504** to receiver IC package **508** of the first device **502**. The cross-talk provided by signal leakage through the device housings and PCB can cause coupling between the first transmitter IC package **506** to the first receiver IC package **508**.

Additionally, signals can propagate through the first PCB **510** where the signals can be received by the first receiver IC package **508**, as illustrated by dashed line **532**.

FIG. **5B** shows an example model system **540** having a first transmitter IC package **542** and a first receiver IC package **544** in the same device. For example, FIG. **5B** can represent a test structure designed to illustrate signal propagation. A portion of a housing **546** laterally separates the first transmitter IC package **542** from the first receiver IC package **544**. In comparison to the first device **502** shown in FIG. **5A**, the model **540** simplifies the system by not introducing a vertical displacement in the *z* direction between the receiver IC package/transmitter IC package and the housing **546**, which corresponds to the housing **514** in FIG. **5A**.

Examples of system parameters used in the computation of the reflection and transmission coefficients plots can include: a distance **548** between the receiver IC package **544** and the transmitter IC package **542**, a depth **552** of the housing **546**, a thickness **550** of the housing **546**, the permittivity of the material (e.g., plastic) of the housing **546** and a loss tangent measured internally at 60 GHz. The loss tangent quantifies dielectric loss of a dielectric material's inherent dissipation of electromagnetic energy, for example, by heat. The values used here reflect that of an exemplary embodiment.

Besides parasitic propagation of signals internally within a device, FIG. **6** shows a side view diagram **600** illustrating a second example of communication between a pair of communication modules, in which signals from a transmitter of a first device are received by a receiver in an adjacent channel of a second device.

Diagram **600** includes a portion of a first device **602** and a second device **604**. The first device **602** includes a first communication module **601**. The first communication module **601** includes a first transmitter IC package **606** and a

second transmitter IC package **608** mounted to a first PCB **610**. Each of the first transmitter IC package **606** and the second transmitter IC package **608** is at least partially encircled by a respective first signal guiding structure **612**, **613** similar to the signal guiding structures described above. The first signal guiding structures **612**, **613** each form a channel extending from the respective IC package to a surface of a first housing **614** of the first device **602**. For example, the first device **602** can be a first mobile phone and the first housing **614** can correspond to the outer case of the first mobile phone. The first device **602** can also be a docking station and the first housing **614** can correspond to an external casing of the docking station.

The second device **604** includes a second communication module **603**. The second communication module **603** includes a first receiver IC package **616** and a second receiver IC package **618** mounted to a second PCB **620**. Each of the first receiver IC package **616** and the second receiver IC package **618** is at least partially encircled by a respective second signal guiding structure **622**, **623**. The second signal guiding structures **622**, **623** each provide a channel extending from the respective IC package to a surface of a second housing **624** of the second device **602**. For example, the second device **602** can be a second mobile phone and the second housing **624** can correspond to the outer case of the second mobile phone. The second device **602** can also be a laptop and the second housing **624** can be the housing of the laptop.

Unintended coupling of signals can also occur between communication modules. In particular, while signals transmitted by the first transmitter IC package **606** are intended for receipt by the first receiver IC package **616**, some signals emitted from the first transmitter IC package **606** may be received by the second receiver IC package **618** of the second device **604**. In particular, signals can propagate through the first housing **614** and/or the second housing **624**, bypassing the first signal guiding structures **612**, **613** and second signal guiding structures **622**, **623**. Once again, the housing (**614** and/or **624**) can serve as a waveguide for the signals emitted from transmitter IC package **606**, as shown by a dotted line **630**. As a result, the cross-talk provided by signal leakage through the device housings can cause unintended coupling between the first transmitter IC package **606** of the first device **602** with the second receiver IC package **616** of the second device **604**.

#### Structures for Reducing Cross-Talk

The example shown in FIGS. **5B** and **5C** can be considered a baseline of signal leakage. The following figures describe the use of additional structures that can reduce this level of signal leakage to provide improved data communication.

FIG. **7A** shows a schematic diagram of structures **742** that reduce or block the parasitic signals from propagating between a first portion **744** of a housing **740** to a second portion **746** of the housing **740**, after a signal **748** is incident (e.g., normally, as shown in FIG. **7A**, or obliquely (not shown)) on the first portion **744**. The structures **742** are formed from a series of alternating first material **750** and second material **752**. The first material **750** may be the same material as the housing **740**, and the second material **752** is a different material from the first material **750**. The first material **760** of the structures **742** can have a width  $d_1$  and the second material **752** of the structures **742** can have a width  $d_2$ . The total width of one unit of the first material **750** and the second material **752** is  $a$ . The structures **742** can be a periodic structure of repeating units **754**, each having a width  $a$ . In other words, the first material **750** within

## 11

structures **742** can have a uniform width of  $d_1$  and the second material **752** within structures **742** can have a uniform width of  $d_2$ . Alternatively, the arrangement of the structures can be non-periodic (i.e., the widths of either the first material or the second material may deviate within one or more portions of the structures **742**.) When the structures are not fully periodic, they generally broaden the effective frequency range at the expense of reducing the magnitude of the effect.

Perturbing the housing **740**, which is formed of a first material (e.g., plastic), by replacing selected portions of the housing **740** with a second material having a different permittivity (e.g., alumina) prevents or reduces the propagation of the signal **748** inside the housing **740**. In other words, the second material (and the intervening first material) can act as a filter. The second material in the selected portions of the housing can be arranged in a periodic fashion. The second material can be formed in shapes such as circular, rod-shaped, or the second material can be formed in trenches or groves defined within the first material.

The signal **748** transmitted through the structures **742** to the second portion **746** of the housing **740** can be compared with the signal **748** propagating in the first portion **744** of the housing. The structures **742** act as filters when they reduce or block the signal **748** from being transmitted to the second portion **746**. FIG. 7B shows a plot **756** of the filter bandwidth (in percent) as a function of the permittivity of the second material **752**.

The width  $d_1$  of the first material **750** can be a quarter of a wavelength of the signal **748** in the first material. The wavelength of the signal in the material is the free-space wavelength divided by the dielectric constant (or permittivity) of the material. Because the material of the first material **750** (and of the housing **740**) is about 2.35, the plot **756** shows a dip to 0% filter bandwidth when the second material **752** also has a permittivity of 2.35. Such a situation is equivalent to a continuous piece of housing **740** that is made of a single uniform material, in which case, no filtering effect is provided. Instead, the housing **740** can additionally act as a dielectric waveguide to guide the signal **748** from the first portion **744** to the second portion **746**, resulting in a filter bandwidth of 0%.

Material can be removed from the housing **740** such that the structures are formed with a second material **752** that is simply air. Air has a relative permittivity ( $\epsilon_r$ ), or dielectric constant, of 1, and the structures **742** in this case provide a filter having a bandwidth of 28%. Plot **756** is independent of frequency. Since the bandwidth is plotted as a % of the signal frequency, it is what is called a normalized quantity. For example, if the transmitted frequency is 50 GHz, choosing a material with a dielectric constant of 5 would yield a bandwidth of  $0.25 \times 50$  GHz, or about 12.5 GHz. The effect of the periodic structure is multiplicative, the shape of the bandpass multiplied by the original bandpass. The structures are designed to be a band-stop filter for blocking a range of frequencies. As the dielectric constant of the second material **752** increases from 1 to match that of the first material **750** (2.35), the filter bandwidth decreases. When the permittivity of the second material **752** increases above 2.35, the filter bandwidth increases again. Alumina has a high dielectric constant of between 9.3-11.5, and the filter bandwidth is above 42% over that range. The plot **756** shows that cross-talk between the transmitter IC package **706** and a receiver IC package **708** can be reduced (e.g., significantly attenuated) when a series of structures are introduced into the housing. The filtering effect accumulate for a number of structures in the series, and this affects the depth of the filter response. One element might block 50% (3 dB) of the

## 12

unwanted propagating signal. Two would block approximately 6 dB ( $0.5 \times 0.5$ ). The effect is cumulative but, because the signal is also spreading, not exactly multiplicative.

FIG. 7C shows a side view diagram **700** illustrating a pair of communication modules including structures for reducing or blocking parasitic signal transmission between or within the communication modules.

Diagram **700** includes a portion of a first device **702** and a second device **704**. The first device **702** includes a first communication module **701**. The first communication module **701** includes a first transceiver IC package **706** and a second transceiver IC package **708** mounted to a first PCB **710**. Each of the first transceiver IC package **706** and the second transceiver IC package **708** is at least partially encircled by a respective first signal guiding structure **712**, **713** similar to the signal guiding structures described above.

The first signal guiding structures **712**, **713** each form a channel extending from the respective transceiver IC package to a surface of a first housing **714** of the first device **702**. For example, the first device **702** can be a first mobile phone and the first housing **714** can correspond to the outer case of the first mobile phone. Only a top portion of the first housing **714** is shown in FIG. 7C. The top portion is supported by a rim portion (not shown). In some embodiments, the first signal guiding structures **712** can serve as part of the rim portion used to support the top portion of the first housing. Alternatively, a different rim portion is used to provide mechanical structural support to the top portion of the housing **714**.

The first device **702** further includes structures **731**. Structures **731** are similar to those shown in FIG. 7A. The structures **731** are spatially positioned adjacent to first housing **714** and between the channels formed by the first signal guiding structures **712** and **713**. The structures **731** are formed within the first housing **714**. The structures **731** can be embedded within the first housing. Even though FIG. 7C shows the structures **731** extending through the entire thickness of the first housing **714**, the structures **731** can extend vertically only partially through a portion of the thickness of the first housing **714** (e.g., half the thickness of the first housing **714**, a quarter of the thickness of the first housing). In some other implementations, the spatial position of the structures **731** can be any suitable position within the electromagnetic field generated by signals leaking from the first transceiver IC package **706** toward the second transceiver package **708**.

The second device **704** includes a second communication module **703**. The second communication module **703** includes a third transceiver IC package **716** and a fourth transceiver IC package **718** mounted to a second PCB **720**. Each of the third transceiver IC package **716** and the fourth transceiver IC package **718** is at least partially encircled by a respective second signal guiding structure **722**, **723**. The second signal guiding structures **722**, **723** each provide a channel extending from the respective transceiver IC package to a surface of a second housing **724** of the second device **704**. For example, the second device **704** can be a second mobile phone and the second housing **724** can correspond to the outer case of the second mobile phone. Alternatively, the second device **704** can be a laptop, and the first device **702** can be a docking station. Only a top portion of the first housing **724** is shown in FIG. 7C. The top portion is supported by a rim portion (not shown). In some embodiments, the second signal guiding structures **722** and **723** can serve as part of the rim portion used to support the top portion of the first housing. Alternatively, a different rim

portion is used to provide mechanical structural support to the top portion of the second housing 724.

The second device 704 further includes structures 733. The structures 733 are spatially positioned adjacent to second housing 724 and between the channels formed by the second signal guiding structures 722 and 723. Similar to the structures 731, in some implementations, the structures 733 are formed at least partially within second housing 724. Even though FIG. 7C shows the structures 733 extending through the entire thickness of the second housing 724, the structures can extend vertically only partially through a portion of the thickness of the second housing 724 (e.g., half the thickness of the second housing 724, a quarter of the thickness of the second housing 724).

For convenience, each IC package is referred to as a transceiver IC package. Each transceiver IC package can also be called a connector. In particular implementations, the transceiver IC package may instead be a transmitter IC package, a receiver IC package, or may be an IC package configured to operate selectively as a transmitter or receiver. Thus, the transceivers can correspond to the paired transmitter IC packages and receiver IC packages of either FIG. 5A or 6.

Structures 731, 733 are configured to disrupt an electromagnetic field associated with signals propagating across channels of the communication modules 701, 703, illustrated by dashed path 734 showing propagation through one or more device housing and dashed path 736 showing propagation of signals through the PCB 710.

FIG. 7D shows a model 758, which is similar to the model 540 shown in FIG. 5B, except for a series of corrugations or structures 762 that populates a portion  $l_c$  of the housing 760. In the embodiment shown in FIG. 7D,  $l_c$  is 75% of the length of the housing 750, which can also be the distance between the transmitter and receiver IC packages 542 and 544. The total number of corrugations or structures 762 within  $l_c$  is  $N_g$ . In the embodiment shown in FIG. 7D, there are 16 corrugations or structures (i.e.,  $N_g=16$ ). The height of the structure 762 is half of the thickness  $t_c$  of the housing 760, and a length of the structure 762 is  $w_c$ . The volume of a repeating unit 754 is  $l_c/N_g \times t_c/2 \times w_c$ .  $l_p$  is the length of the transmitter or receiver IC package, which has a pyramid shape in the model 768 shown in FIG. 7D.  $l_p$  is maintained as a constant in the model and is used for calibration purposes.

FIG. 7E shows a plot 766 of the reflection coefficient S11 between the frequency of 50 GHz to 70 GHz for one embodiment of the model 768 shown in FIG. 7D. Compared to the plot 560 in FIG. 5C for an unperturbed housing having no second material, the presence of the 16 corrugations or structures 762 shifts the minimum of the reflection coefficient S11 (~-8 dB) from 60 GHz in FIG. 5C to about 61 GHz. The maximum of the transmission coefficient S21 drops from -12 dB in FIG. 5C to about -14 dB in FIG. 7E, due to the presence of the 16 structures 762.

FIG. 8 shows a side view diagram 800 illustrating a pair of communication modules including a signal blocking structure and structures for reducing or blocking parasitic signal transmission between or within the communication modules.

Diagram 800 includes a portion of a first device 802 and a second device 804. The first device 802 includes a first communication module 801. The first communication module 801 includes a first transceiver IC package 806 and a second transceiver IC package 808 mounted to a first PCB 810. Each of the first transceiver IC package 806 and the second transceiver IC package 808 is at least partially

encircled by a respective first signal guiding structure 812, 813 similar to the signal guiding structures described above.

The first signal guiding structures 812, 813 each form a channel extending from the respective transceiver IC package to a surface of a first housing 814 of the first device 802. For example, the first device 802 can be a first mobile phone and the first housing 814 can correspond to the outer case of the first mobile phone.

The first device 802 further includes a first blocking structure 830 in addition to the structures 831, which are similar to structures 731 shown in FIG. 7C. The first blocking structure 830 is spatially positioned adjacent to the first PCB 810 and between the channels formed by the first signal guiding structures 812 and 813.

The second device 804 includes a second communication module 803. The second communication module 803 includes a third transceiver IC package 816 and a fourth transceiver IC package 818 mounted to a second PCB 820. Each of the third transceiver IC package 816 and the fourth transceiver IC package 818 is at least partially encircled by a respective second signal guiding structure 822, 823.

The second signal guiding structures 822, 823 each provide a channel extending from the respective transceiver IC package to a surface of a second housing 824 of the second device 802. For example, the second device 802 can be a second mobile phone and the second housing 824 can correspond to the outer case of the second mobile phone.

The second device 804 further includes a second blocking structure 832 in addition to the structures 833, which is similar to structures 733 shown in FIG. 7C. The second blocking structure 832 is spatially positioned adjacent to the second PCB 820 and between the channels formed by the second signal guiding structures 822 and 823.

The blocking structures 830 and 832 can be formed from a material that absorbs electromagnetic radiation, particularly radio frequency electromagnetic radiation including EHF RF electromagnetic radiation. For example, the blocking structure can be composed of a silica-ferrite material, e.g., a material formed by mixing small iron pieces with silicon. In some implementations, an epoxy based ferrite material could be used as a blocking structure having a suitable heat tolerance. Other absorbing materials can be used to form the blocking structure, for example, other ferrite materials or carbon based materials.

The dimensions of the blocking structure can depend on the material used and the dimensions of the communication module, e.g., the spacing between channels or the width of the IC packages. Additionally, the size of the blocking structure can depend on the wavelength of the electromagnetic signals. For example, the blocking structures may extend towards the housing and in some cases may be in contact with the housing or even extend through the housing.

Because the leaking signals are part of an electromagnetic field, propagation can be significantly disrupted even without the blocking structure being directly in a line of sight path of propagation of the signal. Thus, if a first blocking structure 830 is positioned adjacent to the first housing 814, the blocking structure is able to disrupt propagation both through the first housing 814 and the first PCB 810.

Use of the blocking structure 830/832 and structures 831 and 833 can reduce cross-talk generated by unintended coupling. For example, in some implementations, cross talk caused by the unintended coupling can be reduced by up to 10 dB relative to the cross talk without the signal blocking structure. Reducing cross-talk can improve performance of communications between paired transmitter and receiver IC packages. In some implementations, the reduction in cross-

talk can also reduce leakage from the device to outside where they might cause interference with other devices. This reduction in outside leakage can be beneficial to satisfying various regulatory requirements for devices.

Additionally, in some implementations, the presences of the structures **831** and **833** between communication channels can reduce the need for other absorbers such as an absorber that surrounds the signal guiding structures.

As above, each IC package is referred to as a transceiver IC package for convenience. In particular implementations, the transceiver IC package may instead be a transmitter IC package, a receiver IC package, or may be an IC package configured to operate selectively as a transmitter or receiver.

Similar to the signal blocking structures described above with respect to FIG. 7, each of the first and second blocking structures **830**, **832** are configured to disrupt an electromagnetic field associated with signals propagating across channels of the communication modules **801**, **803**, illustrated by dashed path **834** showing propagation through one or more of the device housings and dashed path **836** showing propagation of signals through the PCB **810**.

As described above, propagation can be significantly disrupted even without being positioned directly in a line of sight path between the channels. Thus, although the first blocking structure **830** is positioned adjacent to the first PCB **810**, the blocking structures are able to disrupt propagation both through the housing and the first PCB **810** as shown by paths **834** and **836**.

FIG. 8 shows an example position for signal blocking structures. However other suitable positions can be used. For example, the signal blocking structure can be positioned at a point between the PCB and the housing, e.g., the signal blocking structure can be elevated over the PCB surface by a support structure mounted on the PCB or extending from the housing. In some other implementations, the signal blocking structure is partially embedded within a recess formed in the housing or a recess formed in the PCB. In some implementations, the relative position of the blocking structure with respect to the PCB and the housing can affect the degree of cross-talk reduction from the respective sources. For example, positioning the blocking structure closer to the PCB may result in a greater reduction of electromagnetic signals propagating through the PCB than the reduction of electromagnetic signals propagating through the housing. Similarly, positioning the blocking structure closer to the housing may result in a greater reduction of electromagnetic signals propagating through the housing than the reduction of electromagnetic signals propagating through the PCB. The particular position of the blocking structure can be selected, for example, to optimize the reduction overall or to optimize the reduction from a particular source path, e.g., through the PCB.

FIG. 9 shows a view **900** of a device housing portion **902** incorporating a number of structures **904**. The device housing portion **902** can be, for example, a portion of a device case e.g., for a mobile phone, tablet device, or laptop. In particular, view **900** can represent an interior portion of the device case.

The structures **904** can be formed by removing material from the device housing portion **902** and re-filling voids defined in the device housing portion **902** with a second material. In this way, the exterior surface of the device housing portion **902** can be kept smooth and/or planar, without dents or bumps. Alternatively, the device housing portion **902** can be doped at selected location to the desired structures having a difference dielectric constant from the device housing **902**. The doped material can also be foam.

“Doping” is consistent with common usage in semiconductor physics. In this case, it can include secondary insert molding or equivalent. In addition, the device housing portion **902** can also be produced using other suitable techniques, for example, by 3D printing in which the housing portion **902** can be fabricated to include structures of a second material arranged at specific locations. Various patterns for distributing structures **904** within the device housing portion **902** can be defined through a molding process such as injection molding. Using such a method, the housing will be formed integrally and at the same time as the structures. The structures **904** are positioned such that when the housing portion **902** is positioned over a communication module, the structures **904** are located between the channels of a pair of transceiver IC packages, represented by dashed boxes **906** and **908**.

FIG. 10A shows a side view of a first device **1000** having a first housing **1002** that incorporates a number of structures **1004**. The first device **1000** includes a PCB **1006**. Positioned on PCB **1006** are a first transceiver IC package **1008** and a second transceiver IC package **1010**. The structures **1004** are positioned between the two channels formed by each of the first transceiver IC package **1008** and the second transceiver IC package **1010**. In addition, an absorber **1012** (e.g., a blocking structure like those described with respect to FIG. 8) can be positioned on the PCB **1006**. The first device **1000** is placed in close proximity to a second device **1050** having a second housing **1052** that incorporates a number of structures **1054**. The second device **1050** includes a PCB **1056**. Positioned on PCB **1056** are a third transceiver IC package **1058** and a fourth transceiver IC package **1060**. The structures **1054** are positioned between the two channels formed by each of the third transceiver IC package **1058** and the fourth transceiver IC package **1060**. For example, the first transceiver package **1008** and the third transceiver IC package **1058** jointly form the first channel and the second transceiver IC package **1010** and the fourth transceiver IC package **1060** jointly form the second channel. In addition, an absorber **1062** can be positioned on the PCB **1056**. For simplicity, signal guiding structures, for example, structures **512**, **513**, **522**, and **523** shown in FIG. 5A are not shown in FIG. 10A. In general, the devices include the signal guiding structures. The signal guiding structures can be eliminated if a distance to the absorber structures is short enough. For example, if the absorber is in direct contact with an interior surface of the case, guiding structures are not needed. In some implementations, such a structure may add unnecessary complexity.

FIG. 10B shows a top view of the first device **1000** in close proximity to the second device **1100**. For simplicity, the transceiver IC packages **1008**, **1010**, **1058**, and **1060** are not shown in FIG. 10B.

FIG. 10C shows a plot **1064** of a plot of crosstalk, each curve representing a different degree of suppression. In particular, the transmission coefficient **S21** measures the amount of power transmitted by a transmitter IC package on one portion of the housing that is sensed by a receiver IC package on the other portion of the housing. The housing does not include any arrangement of structures (e.g., periodic structures) or absorbers. The units are dB relative to the desired direct signal, **S21** for example. They are much lower compared to those shown in FIGS. 7E-7K because, unlike the structures shown in FIGS. 7E-7K, the “unfiltered” original crosstalk is the fraction of the direct signal (straight across) that is diverted along the direction of the case. A plot **1066** shows the transmission coefficient **S21** for a housing that includes absorber structures. As can be seen in FIG.

10C, the transmission coefficient S21 is reduced by the presence of the absorbers. A plot 1068 shows the transmission coefficient S21 for a housing that includes a periodic arrangement of structures, similar to structures 1004 and 1054 shown in FIG. 10A. The transmission coefficient S21 is lower when the periodic arrangement of structures are used instead of absorbers. A plot 1070 shows the transmission coefficient when both absorbers and periodic structures are used. The transmission coefficient is lower almost everywhere over the band in this case compared to all plots 1064, 1066, and 1068. Frequency dependence of crosstalk can be due to interactions that involve both constructive and destructive interference. The relevant metric here is the averaged crosstalk, not a single excursion where one curve crosses another. FIG. 10D shows a side view of a first device 2500 having a first housing 2502 that incorporates a number of structures 2504. The first device 2500 includes a PCB 2506. Positioned on PCB 2506 are a first transceiver IC package 2508 and a second transceiver IC package 2510. The structures 2504 are positioned between the two channels formed by each of the first transceiver IC package 2508 and the second transceiver IC package 2510. In addition, an absorber 2512 can be positioned on the PCB 2506. The first device 2500 is placed in close proximity to a second device 2600 having a second housing 2602 that incorporates a number of structures 2604. The second device 2600 includes a PCB 2606. Positioned on PCB 2606 are a third transceiver IC package 2608 and a fourth transceiver IC package 2610. The structures 2604 are positioned between the two channels formed by each of the third transceiver IC package 2608 and the fourth transceiver IC package 2610. For example, the first transceiver package 2508 and the third transceiver IC package 2608 jointly form the first channel and the second transceiver IC package 2510 and the fourth transceiver IC package 2610 jointly form the second channel. In addition, an absorber 2612 can be positioned on the PCB 2606. A dielectric, such as post 2699, may act as a lens and help boost coupling. When the post 2699 is placed in the desired transmission direction, it can help to direct the signal in the correct direction.

FIG. 10E shows a top view of the first device 2500 in close proximity to the second device 2600.

The structures defined in the housing of the devices can also be combined with other signal blocking structures to reduce undesirable cross-talk. For example, the periodic structure may work alone or with absorbers.

FIG. 11A shows a portion 1400 of a housing 1402. Instead of a groove or trench like structure, structures 1404 each having a circular shape can be defined in the housing 1402. Even though the circular shape of structures 1404 shown in FIG. 11A is different from the trench- or groove-shaped structures shown in FIG. 7A. The composition of the material that forms the structures 1404 can be the same as the second material 752 described in FIG. 7A and other figures above. In the embodiment shown in FIG. 11A, the circular structures 1401 have a center-to-center distance 1406 that is constant between adjacent structures. In other words, the structures 1404 shown in FIG. 11A have a regular periodicity. In other embodiments, circular structures can be spaced at irregular intervals from one another, depending on the objectives for the relevant applications.

Each transceiver IC package can also be referred to as a connector. In general, structures can be placed where signal propagation is undesired, such as between connectors or they may surround connectors. FIG. 11B shows an arrangement 1406 of four transceiver IC packages 1408, 1410, 1412, and 1414. Structures 1416, which are made of a

material different from the material of the housing 1418 can be arranged between pairs of connectors as shown in FIG. 11B. The distances between structures 1416 may not be uniform, and the shape of the structures can also differ.

FIG. 11C shows an arrangement 1420 of structures 1424 that are arranged in concentric circles around a connector 1422. The structures 1424 are made of a material different from that of the housing 1426. The concentric circles are arranged alternatively between materials of the housing 1426.

FIG. 11D shows structures 1428 that have a T-shape. Other shapes besides circular, groove/trench, rod and T-shape are possible. A distance 1430 between structures 1428 need not be constant. The size of the structures 1428 also need not be constant.

FIG. 11E shows an example where structures 1430 and 1432 in the form of grooves have different heights. A distance 1434 between each structures 1430 and 1432 also need not be uniform and may be adjusted according to specific needs. Different geometries weight performance parameters differently. Any filter and gain may be favored over bandwidth or vice versa. In this case, the rejection gain may be stronger at a narrow band with a simpler geometry while bandwidth may be favored over a rejection band with more complicated geometries.

In general, corrugations or grooves can be uniform (totally periodic) as shown in FIG. 7C or non-uniform, as shown in FIG. 7A. They can partially or completely penetrate the cover structure, as shown in FIG. 7C and FIG. 7A, respectively. Different groove geometries (number and size) would result in different S11 and S21 values. Better S21 values, such as those lower than -15 dB, demonstrate the enhancement resulting from the groove structures.

The use of structures (e.g., periodic structures having identical repeating units) can help to eliminate the need for absorbers around devices and/or transceiver IC packages. These absorbers can be "picture frame" absorbers that would otherwise surround the devices and/or transceiver IC packages for reducing cross-talk signals. Reducing or eliminating the use of picture frame absorbers can reduce the material volume and free up real estate and lower costs due to the space the materials may take up. For example, an absorber that is arranged to surround the guiding structure may be eliminated when the structures are used. In addition, the material used as to define the structures can be flexibly chosen. For example, the structures can be formed by first removing material from the housing and re-filling the gaps or voids with a second material (e.g., foam, plastics, nylon . . . etc.) to provide a housing having a smooth and/or planar exterior surface. Alternatively, the structures can also be easily implanted within the cases of devices (e.g., plastic cases) for simple integration. Implanting can involve putting the structures in devices. For example, rather than molding the structures directly into the case, the cases may be made with a slot for separately made structures to be inserted therein.

In the example implementations described above, a portion of the housing through which signals pass to or from an IC package of a communication can be formed of a different material than other portions of the housing. For example, in some implementations a portion of the housing can be formed from a metallic material that would inhibit passage of the signals. To allow passage of the signals, a portion of the housing along the signal paths can be formed from another material, for example, an insert of a plastic material that allows signal passage.

A number of embodiments of the invention have been described. Nevertheless, it will be understood that various modifications may be made without departing from the spirit and scope of the invention. Accordingly, other embodiments are within the scope of the following claims.

While this specification contains many specific implementation details, these should not be construed as limitations on the scope of any invention or on the scope of what may be claimed, but rather as descriptions of features that may be specific to particular embodiments of particular inventions. Certain features that are described in this specification in the context of separate embodiments can also be implemented in combination in a single embodiment. Conversely, various features that are described in the context of a single embodiment can also be implemented in multiple embodiments separately or in any suitable subcombination. Moreover, although features may be described above as acting in certain combinations and even initially be claimed as such, one or more features from a claimed combination can in some cases be excised from the combination, and the claimed combination may be directed to a subcombination or variation of a sub combination.

Similarly, while operations are depicted in the drawings in a particular order, this should not be understood as requiring that such operations be performed in the particular order shown or in sequential order, or that all illustrated operations be performed, to achieve desirable results. In certain circumstances, multitasking and parallel processing may be advantageous. Moreover, the separation of various system modules and components in the embodiments described above should not be understood as requiring such separation in all embodiments, and it should be understood that the described program components and systems can generally be integrated together in a single software product or packaged into multiple software products.

Particular embodiments of the subject matter have been described. Other embodiments are within the scope of the following claims. For example, the actions recited in the claims can be performed in a different order and still achieve desirable results. As one example, the processes depicted in the accompanying figures do not necessarily require the particular order shown, or sequential order, to achieve desirable results. In some cases, multitasking and parallel processing may be advantageous.

What is claimed is:

1. An apparatus comprising:

a communications module comprising two or more integrated circuit packages each integrated circuit package including at least one transmitter, receiver, or transceiver; and

a device housing portion for an electronic device, wherein the housing portion comprises a planar portion substantially parallel to a communications module of the device, the planar portion of the housing comprising:

a first region formed from a first material and configured to be in a transmission path of a first electromagnetic signal, associated with a first integrated circuit package, when transmitted to or from the device;

a second region formed from the first material and configured to be in the transmission path of a second electromagnetic signal, associated with a second integrated circuit package, when transmitted to or from the device; and

a third region defined in the housing between the first region and the second region, the third region comprising an arrangement of structures formed from the

first material and a second material, wherein the arrangement of structures includes a plurality of units formed from the second material interleaved with a plurality of units formed from the first material, and wherein the arrangement of structures positioned between the first region and the second region reduce propagation of electromagnetic radiation propagating from the first integrated circuit package to the second integrated circuit package through the housing, wherein the arrangement of structures is oriented such that a direction of the interleaving of the structures is perpendicular to the transmission path of the first and second electromagnetic signals.

2. The apparatus of claim 1, wherein the arrangement of structures comprises a periodic arrangement of the first material and the second material.

3. The apparatus of claim 1, wherein the housing portion of the housing comprising the arrangement of structures has a planar exterior surface.

4. The apparatus of claim 1, wherein the housing portion is configured to be placed over a first connector, the first region is vertically above the first connector, the first connector is configured to transmit electromagnetic radiation through the first region, and the arrangement of the structures comprises a plurality of concentric circles surrounding the first region.

5. The apparatus of claim 1, wherein the housing portion is configured to be placed over a plurality of connectors, the plurality of connectors is configured to transmit electromagnetic radiation through the planar portion, and the arrangement of the structures is disposed in regions of the housing portion that are above gaps between the plurality of connectors.

6. The apparatus of claim 1, wherein a plurality of holes, slots, or trenches is defined in the first material of the top portion of the housing, and the second material fills the plurality of holes to form the arrangement of structures.

7. The apparatus of claim 6, wherein a plurality of slots is defined in the first material, the top portion has a first width and a first length, and the plurality of slots extends across the width of the housing portion.

8. The apparatus of claim 6, wherein a width of the slot filled with the second material is a quarter of a wavelength of the electromagnetic radiation in the second material, and a dimension of a distance between slots in the plurality of slots is a quarter of a wavelength of the electromagnetic radiation in the first material.

9. The apparatus of claim 6, wherein the arrangement of structures is configured to filter electromagnetic radiation having a wavelength between 50 GHz to 70 GHz.

10. The apparatus of claim 9, wherein a bandwidth of the filter is less than 60%.

11. The apparatus of claim 1, wherein a plurality of holes, slots, or trenches filled with the second material is formed integrally with the housing portion by injection molding.

12. The apparatus of claim 1, wherein the first material comprises plastic and the second material comprises foam.

13. The apparatus of claim 1, wherein the electromagnetic radiation is between 50 to 70 GHz and the arrangement of structures reduces a transmission between a first end of the second region and a second end of the second region by more than 40% over a bandwidth of 5 GHz.

14. The apparatus of claim 1, wherein the arrangement of structures formed from the first material and the second material comprises a plurality of structures have one or more different shapes and/or one or more different distances between the plurality of structures.

## 21

15. The apparatus of claim 14, wherein the arrangement of the structures comprises a plurality of structures having different heights.

16. The apparatus of claim 1, wherein the arrangement of structures comprises structures that have heights smaller than a thickness of the planar portion of the housing.

17. A communication device comprising:

a communications module comprising:

a transmitter integrated circuit package, and

a receiver integrated circuit package; and

a housing enclosing the communications module, wherein the housing comprises:

a planar portion parallel to a first surface of the communication module, the planar portion including:

a first region of a first material that permits electromagnetic radiation to be transmitted from the transmitter integrated circuit package and through the first region,

a second region of the first material that permits electromagnetic radiation to be received by the receiver integrated circuit package through the second region, and

a third region comprising a plurality of structures formed of a second material different from the first material, wherein the third region is positioned between the first region and the second region, wherein the plurality of structures are configured to reduce propagation of electromagnetic signals through the housing from the first region to the second region, wherein the plurality of structures defined in the third region of the housing includes a plurality of units formed from the second material interleaved with a plurality of units formed from the first material and arranged perpendicular to a the first surface of the communication module, and wherein the structures are oriented such that a direction of the interleaving of the structures is arranged such that a propagation path through the planar portion of the housing of an electromagnetic signal from the transmitter integrated circuit package to the receiver integrated circuit package crosses one or more of the plurality of structures.

## 22

18. The communication device of claim 17, further comprising an absorber structure, and a printed circuit board on which the transmitter integrated circuit package and the receiver integrated circuit package are mounted, wherein the plurality of structures formed of the second material is configured to reduce cross-talk between the transmitter integrated circuit package and the receiver integrated circuit package.

19. The communication device of claim 17, wherein the communication module is configured to establish a communication channel when a second communication module is placed in proximity to the communication module, and wherein the communication channel is between a transmitter integrated circuit package of the second communication module and the receiver integrated circuit package of the communication module, or between a receiver integrated circuit package of the second communication module and the transmitter integrated circuit package of the communication module.

20. The communication device of claim 17, wherein the plurality of structures formed of a second material comprises a periodic arrangement of the first material and the second material.

21. The communication device of claim 20, wherein a plurality of holes, slots, or trenches is defined in the first material of the housing, and the second material fills the plurality of holes to form the arrangement of structures.

22. The communication device of claim 21, wherein the housing comprising the plurality of structures has a planar exterior surface.

23. The communication device of claim 17, wherein a plurality of slots is defined in a portion of the housing, the housing having a first width and a first length, and the plurality of slots extends across the width of the housing.

24. The communication device of claim 23, wherein a width of the slot filled with the second material is a quarter of a wavelength of the electromagnetic radiation in the second material, and a dimension of a distance between slots in the plurality of slots is a quarter of a wavelength of the electromagnetic radiation in the first material.

25. The communication device of claim 17, wherein the plurality of structures is configured to filter electromagnetic radiation having a wavelength between 50 GHz to 70 GHz.

UNITED STATES PATENT AND TRADEMARK OFFICE  
**CERTIFICATE OF CORRECTION**

PATENT NO. : 10,454,526 B1  
APPLICATION NO. : 15/398588  
DATED : October 22, 2019  
INVENTOR(S) : Ahmed Khidre, Mohamed Sameh Mahmoud and Eric Sweetman

Page 1 of 1

It is certified that error appears in the above-identified patent and that said Letters Patent is hereby corrected as shown below:

In the Claims

Column 21, Line 21, in Claim 17, delete "ration" and insert -- radiation --.

Column 21, Line 36, in Claim 17, after "to" delete "a".

Signed and Sealed this  
Fifteenth Day of September, 2020

Andrei Iancu
