

US011158337B2

(12) **United States Patent**  
**Bradshaw**

(10) **Patent No.:** **US 11,158,337 B2**  
(45) **Date of Patent:** **\*Oct. 26, 2021**

(54) **TAPE CARTRIDGE HAVING TAPE MEDIA HAVING SYNERGISTIC MAGNETIC RECORDING LAYER AND UNDERLAYER**

(58) **Field of Classification Search**  
None  
See application file for complete search history.

(71) Applicant: **International Business Machines Corporation**, Armonk, NY (US)

**G11B 5/73** (2006.01)

A tape cartridge, according to one approach, includes a housing, and a magnetic recording tape at least partially stored in the housing. The magnetic recording tape including a recording layer having encapsulated nanoparticles each comprising a magnetic nanoparticle encapsulated by an encapsulating layer, and a polymeric binder binding the encapsulated nanoparticles. A tape cartridge, according to another approach, includes a housing, and a magnetic recording tape at least partially stored in the housing. The magnetic recording tape include an underlayer having encapsulated nanoparticles each comprising a magnetic nanoparticle encapsulated by an aromatic polymer, and a polymeric binder binding the encapsulated nanoparticles.

**TAPE CARTRIDGE HAVING TAPE MEDIA  
HAVING SYNERGISTIC MAGNETIC  
RECORDING LAYER AND UNDERLAYER**

BACKGROUND

The present invention relates to data storage systems, and more particularly, this invention relates to magnetic recording layers for tape media.

In magnetic storage systems, magnetic transducers read data from and write data onto magnetic recording media. Data is written on the magnetic recording media by moving a magnetic recording transducer to a position over the media where the data is to be stored. The magnetic recording transducer then generates a magnetic field, which encodes the data into the magnetic media. Data is read from the media by similarly positioning the magnetic read transducer and then sensing the magnetic field of the magnetic media. Read and write operations may be independently synchronized with the movement of the media to ensure that the data can be read from and written to the desired location on the media.

An important and continuing goal in the data storage industry is that of increasing the density of data stored on a medium. For tape storage systems, that goal has led to increasing the track and linear bit density on recording tape, and decreasing the thickness of the magnetic tape medium. However, the development of small footprint, higher performance tape drive systems has created various challenges ranging from the design of tape head assemblies for use in such systems to dealing with tape dimensional instability.

SUMMARY

A tape cartridge, according to one approach, includes a housing, and a magnetic recording tape at least partially stored in the housing. The magnetic recording tape including a recording layer having encapsulated nanoparticles each comprising a magnetic nanoparticle encapsulated by an encapsulating layer, and a polymeric binder binding the encapsulated nanoparticles.

Various benefits of a tape cartridge having the foregoing construction and various combinations of features disclosed herein include, but are not limited to, one or more of: thinner recording layer, more uniform magnetic particle dispersion in the recording layer, smoother, less turbid interface between the underlayer and recording layer, higher glass transition temperature, lower occurrence or essential elimination of voids of magnetic particles in the recording layer, etc. Each of these benefits results in a magnetic recording product, such as tape, that exhibits characteristics such as, but not limited to, one or more of: improved tear resistance, higher recording resolution down to and below 1 nm, lower noise resulting in a higher signal to noise ratio, etc.

In another aspect, no wear particles are present in the magnetic recording tape. Such wear particles have been found to constitute an increasingly intolerable defect and source of damage to the shrinking read and write structures in current and future recording heads.

A tape cartridge, according to another approach, includes a housing, and a magnetic recording tape at least partially stored in the housing. The magnetic recording tape include an underlayer having encapsulated nanoparticles each comprising a magnetic nanoparticle encapsulated by an aromatic polymer, and a polymeric binder binding the encapsulated nanoparticles.

Various benefits of a tape cartridge having the foregoing construction and various combinations of features disclosed herein include, but are not limited to, one or more of: thinner recording layer, more uniform magnetic particle dispersion in the recording layer, smoother, less turbid interface between the underlayer and recording layer, higher glass transition temperature, lower occurrence or essential elimination of voids of magnetic particles in the recording layer, etc. Each of these benefits results in a magnetic recording product, such as tape, that exhibits characteristics such as, but not limited to, one or more of: improved tear resistance, higher recording resolution down to and below 1 nm, lower noise resulting in a higher signal to noise ratio, etc.

Aromatic polymers are preferred as the encapsulating layer, because the aromatic ring structure(s) that encapsulates the surface of the magnetic nanoparticle. Aromatic rings have a very beneficial behavior, particularly with chemically reactive metal oxides such as chromium oxide, due to the unique characteristic of aromaticity in such molecules which offers improved stability and some magnetic shielding at the surface of the magnetic nanoparticles if properly aligned with the magnetic axes of the magnetic nanoparticles. For example, the aromatic ring structures can act as a magnetic field modifier due to their unique molecular electronic structure and ability to moderate an external magnetic field. Aromatic polymers also provide magnetic shielding at the surface of the pigment, and help isolate the magnetic nanoparticles from other particles to improve the independent switching of the encapsulated nanoparticles, resulting in higher bit resolution.

In one aspect, the underlayer is electrically conductive. The electrically conductive characteristic of the underlayer assists in dissipating the charge, e.g., by transporting the charge to a hub coupled to a ground, thereby minimizing charge traveling into the head and consequently lessening the risk of condensed liquid water forming a conductive path between the tape and head surface that provides a path for the electrochemical corrosion of the recording head structures.

In another aspect, no wear particles are present in the underlayer. Such wear particles have been found to constitute an increasingly intolerable defect and source of damage to the shrinking read and write structures in current and future recording heads.

A tape cartridge, according to another approach, includes a housing, and a magnetic recording tape at least partially stored in the housing. The magnetic recording tape includes an underlayer and a recording layer above the underlayer. The underlayer has first encapsulated nanoparticles each comprising a magnetic nanoparticle encapsulated by an aromatic polymer, and a polymeric binder binding the first encapsulated nanoparticles. The recording layer has second encapsulated nanoparticles each comprising a magnetic nanoparticle encapsulated by an encapsulating layer, and a polymeric binder binding the second encapsulated nanoparticles.

Various benefits of a tape cartridge having the foregoing construction and various combinations of features disclosed herein include, but are not limited to, one or more of: thinner recording layer, more uniform magnetic particle dispersion in the recording layer, smoother, less turbid interface between the underlayer and recording layer, higher glass transition temperature, lower occurrence or essential elimination of voids of magnetic particles in the recording layer, etc. Each of these benefits results in a magnetic recording product, such as tape, that exhibits characteristics such as, but not limited to, one or more of: improved tear resistance,

higher recording resolution down to and below 1 nm, lower noise resulting in a higher signal to noise ratio, etc.

Other aspects and approaches of the present invention will become apparent from the following detailed description, which, when taken in conjunction with the drawings, illustrate by way of example the principles of the invention.

#### BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1A is a schematic diagram of a simplified tape drive system.

FIG. 1B is a schematic diagram of a tape cartridge according to one aspect of the present invention.

FIG. 2A illustrates a side view of a flat-lapped, bi-directional, two-module magnetic tape head according to one aspect of the present invention.

FIG. 2B is a tape bearing surface view taken from Line 2B of FIG. 2A.

FIG. 2C is a detailed view taken from Circle 2C of FIG. 2B.

FIG. 2D is a detailed view of a partial tape bearing surface of a pair of modules.

FIG. 3 is a partial tape bearing surface view of a magnetic head having a write-read-write configuration.

FIG. 4 is a partial tape bearing surface view of a magnetic head having a read-write-read configuration.

FIG. 5 is a side view of a magnetic tape head with three modules where the modules all generally lie along about parallel planes.

FIG. 6 is a side view of a magnetic tape head with three modules in a tangent (angled) configuration.

FIG. 7 is a side view of a magnetic tape head with three modules in an overwrap configuration.

FIGS. 8A-8C are schematics depicting the principles of tape tenting.

FIG. 9 is a representational diagram of files and indexes stored on a magnetic tape in accordance with one aspect of the present invention.

FIG. 10 is a partial cross-sectional view of the basic structure of a magnetic recording medium, in accordance with various approaches.

FIG. 11 is a plot depicting Dynamic Mechanical Analysis (DMA) of coatings to determine the Critical Pigment Volume Concentration (CPVC), according to various approaches.

FIG. 12 is a transmission electron microscope (TEM) image of a cross section of a conventional recording tape.

#### DETAILED DESCRIPTION

The following description is made for the purpose of illustrating the general principles of the present invention and is not meant to limit the inventive concepts claimed herein. Further, particular features described herein can be used in combination with other described features in each of the various possible combinations and permutations.

Unless otherwise specifically defined herein, all terms are to be given their broadest possible interpretation including meanings implied from the specification as well as meanings understood by those skilled in the art and/or as defined in dictionaries, treatises, etc.

It must also be noted that, as used in the specification and the appended claims, the singular forms “a,” “an” and “the” include plural referents unless otherwise specified.

The following description discloses various configurations of layers particularly useful in magnetic recording media, as well as methods for forming the layers.

In one general approach, a tape cartridge includes a housing, and a magnetic recording tape at least partially stored in the housing. The magnetic recording tape including a recording layer having encapsulated nanoparticles each comprising a magnetic nanoparticle encapsulated by an encapsulating layer, and a polymeric binder binding the encapsulated nanoparticles.

In another general approach, a tape cartridge includes a housing, and a magnetic recording tape at least partially stored in the housing. The magnetic recording tape include an underlayer having encapsulated nanoparticles each comprising a magnetic nanoparticle encapsulated by an aromatic polymer, and a polymeric binder binding the encapsulated nanoparticles.

In another general approach, a tape cartridge includes a housing, and a magnetic recording tape at least partially stored in the housing. The magnetic recording tape includes an underlayer and a recording layer above the underlayer. The underlayer has first encapsulated nanoparticles each comprising a magnetic nanoparticle encapsulated by an aromatic polymer, and a polymeric binder binding the first encapsulated nanoparticles. The recording layer has second encapsulated nanoparticles each comprising a magnetic nanoparticle encapsulated by an encapsulating layer, and a polymeric binder binding the second encapsulated nanoparticles.

#### Illustrative Operating Environment

FIG. 1A illustrates a simplified tape drive 100 of a tape-based data storage system, which may be employed in the context of the present invention. While one specific implementation of a tape drive is shown in FIG. 1A, it should be noted that the approaches described herein may be implemented in the context of any type of tape drive system.

As shown, a tape supply cartridge 120 and a take-up reel 121 are provided to support a tape 122. One or more of the reels may form part of a removable cartridge and are not necessarily part of the tape drive 100. The tape drive, such as that illustrated in FIG. 1A, may further include drive motor(s) to drive the tape supply cartridge 120 and the take-up reel 121 to move the tape 122 over a tape head 126 of any type. Such head may include an array of readers, writers, or both.

Guides 125 guide the tape 122 across the tape head 126. Such tape head 126 is in turn coupled to a controller 128 via a cable 130. The controller 128, may be or include a processor and/or any logic for controlling any subsystem of the drive 100. For example, the controller 128 typically controls head functions such as servo following, data writing, data reading, etc. The controller 128 may include at least one servo channel and at least one data channel, each of which include data flow processing logic configured to process and/or store information to be written to and/or read from the tape 122. The controller 128 may operate under logic known in the art, as well as any logic disclosed herein, and thus may be considered as a processor for any of the descriptions of tape drives included herein, in various approaches. The controller 128 may be coupled to a memory 136 of any known type, which may store instructions executable by the controller 128. Moreover, the controller 128 may be configured and/or programmable to perform or control some or all of the methodology presented herein. Thus, the controller 128 may be considered to be configured to perform various operations by way of logic programmed into one or more chips, modules, and/or blocks; software, firmware, and/or other instructions being available to one or more processors; etc., and combinations thereof.

The cable **130** may include read/write circuits to transmit data to the tape head **126** to be recorded on the tape **122** and to receive data read by the tape head **126** from the tape **122**. An actuator **132** controls position of the tape head **126** relative to the tape **122**.

An interface **134** may also be provided for communication between the tape drive **100** and a host (internal or external) to send and receive the data and for controlling the operation of the tape drive **100** and communicating the status of the tape drive **100** to the host, all as will be understood by those of skill in the art.

FIG. 1B illustrates an exemplary tape cartridge **150**, which in various approaches may include any configuration of the magnetic recording media described herein in tape form. Such tape cartridge **150** may be used with a system such as that shown in FIG. 1A. As shown, the tape cartridge **150** includes a housing **152**, a tape **122** in the housing **152**, and an optional nonvolatile memory **156** coupled to the housing **152**. In some approaches, the nonvolatile memory **156** may be embedded inside the housing **152**, as shown in FIG. 1B. In more approaches, the nonvolatile memory **156** may be attached to the inside or outside of the housing **152** without modification of the housing **152**. For example, the nonvolatile memory may be embedded in a self-adhesive label **154**. In one preferred approach, the nonvolatile memory **156** may be solid state memory (e.g., Flash memory), read-only memory (ROM) device, etc., embedded into or coupled to the inside or outside of the tape cartridge **150**. The nonvolatile memory is accessible by the tape drive and the tape operating software (the driver software), and/or another device.

By way of example, FIG. 2A illustrates a side view of a flat-lapped, bi-directional, two-module magnetic tape head **200** which may be implemented in the context of the present invention. As shown, the head includes a pair of bases **202**, each equipped with a module **204**, and fixed at a small angle  $\alpha$  with respect to each other. The bases may be “U-beams” that are adhesively coupled together. Each module **204** includes a substrate **204A** and a closure **204B** with a thin film portion, commonly referred to as a “gap” in which the readers and/or writers **206** are formed. In use, a tape **208** is moved over the modules **204** along a media (tape) bearing surface **209** in the manner shown for reading and writing data on the tape **208** using the readers and writers. The wrap angle  $\theta$  of the tape **208** at edges going onto and exiting the flat media support surfaces **209** are usually between about 0.1 degree and about 3 degrees.

The substrates **204A** are typically constructed of a wear resistant material, such as a ceramic. The closures **204B** may be made of the same or similar ceramic as the substrates **204A**.

The readers and writers may be arranged in a piggyback or merged configuration. An illustrative piggybacked configuration comprises a (magnetically inductive) writer transducer on top of (or below) a (magnetically shielded) reader transducer (e.g., a magnetoresistive reader, etc.), wherein the poles of the writer and the shields of the reader are generally separated. An illustrative merged configuration comprises one reader shield in the same physical layer as one writer pole (hence, “merged”). The readers and writers may also be arranged in an interleaved configuration. Alternatively, each array of channels may be readers or writers only. Any of these arrays may contain one or more servo track readers for reading servo data on the medium.

FIG. 2B illustrates the tape bearing surface **209** of one of the modules **204** taken from Line 2B of FIG. 2A. A representative tape **208** is shown in dashed lines. The

module **204** is preferably long enough to be able to support the tape as the head steps between data bands.

In this example, the tape **208** includes 4 to 32 data bands, e.g., with 16 data bands and 17 servo tracks **210**, as shown in FIG. 2B on a one-half inch wide tape **208**. The data bands are defined between servo tracks **210**. Each data band may include a number of data tracks, for example 1024 data tracks (not shown). During read/write operations, the readers and/or writers **206** are positioned to specific track positions within one of the data bands. Outer readers, sometimes called servo readers, read the servo tracks **210**. The servo signals are in turn used to keep the readers and/or writers **206** aligned with a particular set of tracks during the read/write operations.

FIG. 2C depicts a plurality of readers and/or writers **206** formed in a gap **218** on the module **204** in Circle 2C of FIG. 2B. As shown, the array of readers and writers **206** includes, for example, 16 writers **214**, 16 readers **216** and two servo readers **212**, though the number of elements may vary. Illustrative approaches include 8, 16, 32, 40, and 64 active readers and/or writers **206** per array, and alternatively interleaved designs having odd numbers of reader or writers such as 17, 25, 33, etc. An illustrative approach includes 32 readers per array and/or 32 writers per array, where the actual number of transducer elements could be greater, e.g., 33, 34, etc. This allows the tape to travel more slowly, thereby reducing speed-induced tracking and mechanical difficulties and/or execute fewer “wraps” to fill or read the tape. While the readers and writers may be arranged in a piggyback configuration as shown in FIG. 2C, the readers **216** and writers **214** may also be arranged in an interleaved configuration. Alternatively, each array of readers and/or writers **206** may be readers or writers only, and the arrays may contain one or more servo readers **212**. As noted by considering FIGS. 2A and 2B-2C together, each module **204** may include a complementary set of readers and/or writers **206** for such things as bi-directional reading and writing, read-while-write capability, backward compatibility, etc.

FIG. 2D shows a partial tape bearing surface view of complementary modules of a magnetic tape head **200** according to one approach. In this approach, each module has a plurality of read/write (R/W) pairs in a piggyback configuration formed on a common substrate **204A** and an optional electrically insulative insulating layer **236**. The writers **214** and the readers **216** are aligned parallel to an intended direction of travel of a tape medium thereacross to form an R/W pair, exemplified by R/W pairs **222**. Note that the intended direction of tape travel is sometimes referred to herein as the direction of tape travel, and such terms may be used interchangeably. Such direction of tape travel may be inferred from the design of the system, e.g., by examining the guides; observing the actual direction of tape travel relative to the reference point; etc. Moreover, in a system operable for bi-direction reading and/or writing, the direction of tape travel in both directions is typically parallel and thus both directions may be considered equivalent to each other.

Several R/W pairs **222** may be present, such as 8, 16, 32 pairs, etc. The R/W pairs **222** as shown are linearly aligned in a direction generally perpendicular to a direction of tape travel thereacross. However, the pairs may also be aligned diagonally, etc. Servo readers **212** are positioned on the outside of the array of R/W pairs, the function of which is well known.

Generally, the magnetic tape medium moves in either a forward or reverse direction as indicated by arrow **220**. The magnetic tape medium and head assembly **200** operate in a

transducing relationship in the manner well-known in the art. The head assembly **200** includes two thin-film modules **224** and **226** of generally identical construction.

Modules **224** and **226** are joined together with a space present between closures **204B** thereof (partially shown) to form a single physical unit to provide read-while-write capability by activating the writer of the leading module and reader of the trailing module aligned with the writer of the leading module parallel to the direction of tape travel relative thereto. When a module **224**, **226** of a magnetic tape head **200** is constructed, layers are formed in the gap **218** created above an electrically conductive substrate **204A** (partially shown), e.g., of AlTiC, in generally the following order for the R/W pairs **222**: an insulating layer **236**, a first shield **232** typically of an iron alloy such as NiFe (–), cobalt zirconium tantalum (CZT) or Al–Fe–Si (Sendust), a sensor **234** for sensing a data track on a magnetic medium, a second shield **238** typically of a nickel-iron alloy (e.g., ~80/20 at % NiFe, also known as permalloy), first and second writer poles **228**, **230**, and a coil (not shown). The sensor may be of any known type, including those based on magnetoresistive (MR), GMR, AMR, tunneling magnetoresistance (TMR), etc.

The first and second writer poles **228**, **230** may be fabricated from high magnetic moment materials such as ~45/55 NiFe. Note that these materials are provided by way of example only, and other materials may be used. Additional layers such as insulation between the shields and/or pole tips and an insulation layer surrounding the sensor may be present. Illustrative materials for the insulation include alumina and other oxides, insulative polymers, etc.

The configuration of the tape head **126** may include multiple module, preferably three or more. In a write-read-write (W-R-W) head, outer modules for writing flank one or more inner modules for reading. Referring to FIG. 3, depicting a W-R-W configuration, the outer modules **252**, **256** each include one or more arrays of writers **260**. The inner module **254** of FIG. 3 includes one or more arrays of readers **258** in a similar configuration. Variations of a multi-module head include a R-W-R head (FIG. 4), a R-R-W head, a W-W-R head, etc. In yet other variations, one or more of the modules may have read/write pairs of transducers. Moreover, more than three modules may be present. In further approaches, two outer modules may flank two or more inner modules, e.g., in a W-R-R-W, a R-W-W-R arrangement, etc. For simplicity, a W-R-W head is used primarily herein to exemplify aspects of the present invention. One skilled in the art apprised with the teachings herein will appreciate how permutations of the present invention would apply to configurations other than a W-R-W configuration.

FIG. 5 illustrates a magnetic head **126** according to one approach that includes first, second and third modules **302**, **304**, **306** each having a tape bearing surface **308**, **310**, **312** respectively, which may be flat, contoured, etc. Note that while the term “tape bearing surface” appears to imply that the surface facing the tape **315** is in physical contact with the tape bearing surface, this is not necessarily the case. Rather, only a portion of the tape may be in contact with the tape bearing surface, constantly or intermittently, with other portions of the tape riding (or “flying”) above the tape bearing surface on a layer of air, sometimes referred to as an “air bearing”. The first module **302** will be referred to as the “leading” module as it is the first module encountered by the tape in a three module design for tape moving in the indicated direction. The third module **306** will be referred to as the “trailing” module. The trailing module follows the middle module and is the last module seen by the tape in a

three module design. The leading and trailing modules **302**, **306** are referred to collectively as outer modules. Also note that the outer modules **302**, **306** will alternate as leading modules, depending on the direction of travel of the tape **315**.

In one approach, the tape bearing surfaces **308**, **310**, **312** of the first, second and third modules **302**, **304**, **306** lie on about parallel planes (which is meant to include parallel and nearly parallel planes, e.g., between parallel and tangential as in FIG. 6), and the tape bearing surface **310** of the second module **304** is above the tape bearing surfaces **308**, **312** of the first and third modules **302**, **306**. As described below, this has the effect of creating the desired wrap angle  $\alpha_2$  of the tape relative to the tape bearing surface **310** of the second module **304**.

Where the tape bearing surfaces **308**, **310**, **312** lie along parallel or nearly parallel yet offset planes, intuitively, the tape should peel off of the tape bearing surface **308** of the leading module **302**. However, the vacuum created by a skiving edge **318** of the leading module **302** has been found by experimentation to be sufficient to keep the tape adhered to the tape bearing surface **308** of the leading module **302**. A trailing edge **320** of the leading module **302** (the end from which the tape leaves the leading module **302**) is the approximate reference point which defines the wrap angle  $\alpha_2$  over the tape bearing surface **310** of the second module **304**. The tape stays in close proximity to the tape bearing surface until close to the trailing edge **320** of the leading module **302**. Accordingly, transducers **322** may be located near the trailing edges of the outer modules **302**, **306**. These approaches are particularly adapted for write-read-write applications.

A benefit of this and other aspects described herein is that, because the outer modules **302**, **306** are fixed at a determined offset from the second module **304**, the inner wrap angle  $\alpha_2$  is fixed when the modules **302**, **304**, **306** are coupled together or are otherwise fixed into a head. The inner wrap angle  $\alpha_2$  is approximately  $\tan^{-1}(\delta/W)$  where  $\delta$  is the height difference between the planes of the tape bearing surfaces **308**, **310** and  $W$  is the width between the opposing ends of the tape bearing surfaces **308**, **310**. An illustrative inner wrap angle  $\alpha_2$  is in a range of about 0.3° to about 1.1°, though can be any angle required by the design.

Beneficially, the inner wrap angle  $\alpha_2$  on the side of the module **304** receiving the tape (leading edge) will be larger than the inner wrap angle  $\alpha_3$  on the trailing edge, as the tape **315** rides above the trailing module **306**. This difference is generally beneficial as a smaller  $\alpha_3$  tends to oppose what has heretofore been a steeper exiting effective wrap angle.

Note that the tape bearing surfaces **308**, **312** of the outer modules **302**, **306** are positioned to achieve a negative wrap angle at the trailing edge **320** of the leading module **302**. This is generally beneficial in helping to reduce friction due to contact with the trailing edge **320**, provided that proper consideration is given to the location of the crowbar region that forms in the tape where it peels off the head. This negative wrap angle also reduces flutter and scrubbing damage to the elements on the leading module **302**. Further, at the trailing module **306**, the tape **315** flies over the tape bearing surface **312** so there is virtually no wear on the elements when tape is moving in this direction. Particularly, the tape **315** entrains air and so will not significantly ride on the tape bearing surface **312** of the third module **306** (some contact may occur). This is permissible, because the leading module **302** is writing while the trailing module **306** is idle.

Writing and reading functions are performed by different modules at any given time. In one approach, the second

module **304** includes a plurality of data and optional servo readers **331** and no writers. The first and third modules **302**, **306** include a plurality of writers **322** and no data readers, with the exception that the outer modules **302**, **306** may include optional servo readers. The servo readers may be used to position the head during reading and/or writing operations. The servo reader(s) on each module are typically located towards the end of the array of readers or writers.

By having only readers or side by side writers and servo readers in the gap between the substrate and closure, the gap length can be substantially reduced. Typical heads have piggybacked readers and writers, where the writer is formed above each reader. A typical gap is 20-35 microns. However, irregularities on the tape may tend to droop into the gap and create gap erosion. Thus, the smaller the gap is the better. The smaller gap enabled herein exhibits fewer wear related problems.

In some approaches, the second module **304** has a closure, while the first and third modules **302**, **306** do not have a closure. Where there is no closure, preferably a hard coating is added to the module. One preferred coating is diamond-like carbon (DLC).

In the approach shown in FIG. 5, the first, second, and third modules **302**, **304**, **306** each have a closure **332**, **334**, **336**, which extends the tape bearing surface of the associated module, thereby effectively positioning the read/write elements away from the edge of the tape bearing surface. The closure **332** on the second module **304** can be a ceramic closure of a type typically found on tape heads. The closures **334**, **336** of the first and third modules **302**, **306**, however, may be shorter than the closure **332** of the second module **304** as measured parallel to a direction of tape travel over the respective module. This enables positioning the modules closer together. One way to produce shorter closures **334**, **336** is to lap the standard ceramic closures of the second module **304** an additional amount. Another way is to plate or deposit thin film closures above the elements during thin film processing. For example, a thin film closure of a hard material such as Sendust or nickel-iron alloy (e.g., 45/55) can be formed on the module.

With reduced-thickness ceramic or thin film closures **334**, **336** or no closures on the outer modules **302**, **306**, the write-to-read gap spacing can be reduced to less than about 1 mm, e.g., about 0.75 mm, or 50% less than commonly-used linear tape open (LTO) tape head spacing. The open space between the modules **302**, **304**, **306** can still be set to approximately 0.5 to 0.6 mm, which in some approaches is ideal for stabilizing tape motion over the second module **304**.

Depending on tape tension and stiffness, it may be desirable to angle the tape bearing surfaces of the outer modules relative to the tape bearing surface of the second module. FIG. 6 illustrates an apparatus where the modules **302**, **304**, **306** are in a tangent or nearly tangent (angled) configuration. Particularly, the tape bearing surfaces of the outer modules **302**, **306** are about parallel to the tape at the desired wrap angle  $\alpha_2$  of the second module **304**. In other words, the planes of the tape bearing surfaces **308**, **312** of the outer modules **302**, **306** are oriented at about the desired wrap angle  $\alpha_2$  of the tape **315** relative to the second module **304**. The tape will also pop off of the trailing module **306** in this approach, thereby reducing wear on the elements in the trailing module **306**. These approaches are particularly useful for write-read-write applications. Additional aspects of these approaches are similar to those given above.

Typically, the tape wrap angles may be set about midway between the approaches shown in FIGS. 5 and 6.

FIG. 7 illustrates an apparatus where the modules **302**, **304**, **306** are in an overwrap configuration. Particularly, the tape bearing surfaces **308**, **312** of the outer modules **302**, **306** are angled slightly more than the tape **315** when set at the desired wrap angle  $\alpha_2$  relative to the second module **304**. In this approach, the tape does not pop off of the trailing module, allowing it to be used for writing or reading. Accordingly, the leading and middle modules can both perform reading and/or writing functions while the trailing module can read any just-written data. Thus, these approaches are preferred for write-read-write, read-write-read, and write-write-read applications. In the latter approaches, closures should be wider than the tape canopies for ensuring read capability. The wider closures may require a wider gap-to-gap separation. Therefore, a preferred approach has a write-read-write configuration, which may use shortened closures that thus allow closer gap-to-gap separation.

Additional aspects of the approaches shown in FIGS. 6 and 7 are similar to those given above.

A 32 channel version of a multi-module tape head **126** may use cables **350** having leads on the same or smaller pitch as current 16 channel piggyback LTO modules, or alternatively the connections on the module may be organ-keyboarded for a 50% reduction in cable span. Over-under, writing pair unshielded cables may be used for the writers, which may have integrated servo readers.

The outer wrap angles  $\alpha_1$  may be set in the drive, such as by guides of any type known in the art, such as adjustable rollers, slides, etc. or alternatively by outriggers, which are integral to the head. For example, rollers having an offset axis may be used to set the wrap angles. The offset axis creates an orbital arc of rotation, allowing precise alignment of the wrap angle  $\alpha_1$ .

To assemble any of the approaches described above, conventional u-beam assembly can be used. Accordingly, the mass of the resultant head may be maintained or even reduced relative to heads of previous generations. In other approaches, the modules may be constructed as a unitary body. Those skilled in the art, armed with the present teachings, will appreciate that other known methods of manufacturing such heads may be adapted for use in constructing such heads. Moreover, unless otherwise specified, processes and materials of types known in the art may be adapted for use in various approaches in conformance with the teachings herein, as would become apparent to one skilled in the art upon reading the present disclosure.

As a tape is run over a module, it is preferred that the tape passes sufficiently close to magnetic transducers on the module such that reading and/or writing is efficiently performed, e.g., with a low error rate. According to some approaches, tape tenting may be used to ensure the tape passes sufficiently close to the portion of the module having the magnetic transducers. To better understand this process, FIGS. 8A-8C illustrate the principles of tape tenting. FIG. 8A shows a module **800** having an upper tape bearing surface **802** extending between opposite edges **804**, **806**. A stationary tape **808** is shown wrapping around the edges **804**, **806**. As shown, the bending stiffness of the tape **808** lifts the tape off of the tape bearing surface **802**. Tape tension tends to flatten the tape profile, as shown in FIG. 8A. Where tape tension is minimal, the curvature of the tape is more parabolic than shown.

FIG. 8B depicts the tape **808** in motion. The leading edge, i.e., the first edge the tape encounters when moving, may serve to skive air from the tape, thereby creating a subambient air pressure between the tape **808** and the tape bearing

## 11

surface **802**. In FIG. **8B**, the leading edge is the left edge and the right edge is the trailing edge when the tape is moving left to right. As a result, atmospheric pressure above the tape urges the tape toward the tape bearing surface **802**, thereby creating tape tenting proximate each of the edges. The tape bending stiffness resists the effect of the atmospheric pressure, thereby causing the tape tenting proximate both the leading and trailing edges. Modeling predicts that the two tents are very similar in shape.

FIG. **8C** depicts how the subambient pressure urges the tape **808** toward the tape bearing surface **802** even when a trailing guide **810** is positioned above the plane of the tape bearing surface.

It follows that tape tenting may be used to direct the path of a tape as it passes over a module. As previously mentioned, tape tenting may be used to ensure the tape passes sufficiently close to the portion of the module having the magnetic transducers, preferably such that reading and/or writing is efficiently performed, e.g., with a low error rate.

Magnetic tapes may be stored in tape cartridges that are, in turn, stored at storage slots or the like inside a data storage library. The tape cartridges may be stored in the library such that they are accessible for physical retrieval. In addition to magnetic tapes and tape cartridges, data storage libraries may include data storage drives that store data to, and/or retrieve data from, the magnetic tapes. Moreover, tape libraries and the components included therein may implement a file system which enables access to tape and data stored on the tape.

File systems may be used to control how data is stored in, and retrieved from, memory. Thus, a file system may include the processes and data structures that an operating system uses to keep track of files in memory, e.g., the way the files are organized in memory. Linear Tape File System (LTFS) is an exemplary format of a file system that may be implemented in a given library in order to enable access to compliant tapes. It should be appreciated that various aspects described herein can be implemented with a wide range of file system formats, including for example IBM Spectrum Archive Library Edition (LTFS LE). However, to provide a context, and solely to assist the reader, some of the approaches below may be described with reference to LTFS which is a type of file system format. This has been done by way of example only, and should not be deemed limiting on the invention defined in the claims.

A tape cartridge may be “loaded” by inserting the cartridge into the tape drive, and the tape cartridge may be “unloaded” by removing the tape cartridge from the tape drive. Once loaded in a tape drive, the tape in the cartridge may be “threaded” through the drive by physically pulling the tape (the magnetic recording portion) from the tape cartridge, and passing it above a magnetic head of a tape drive. Furthermore, the tape may be attached on a take-up reel (e.g., see **121** of FIG. **1A** above) to move the tape over the magnetic head.

Once threaded in the tape drive, the tape in the cartridge may be “mounted” by reading metadata on a tape and bringing the tape into a state where the LTFS is able to use the tape as a constituent component of a file system. Moreover, in order to “unmount” a tape, metadata is preferably first written on the tape (e.g., as an index), after which the tape may be removed from the state where the LTFS is allowed to use the tape as a constituent component of a file system. Finally, to “unthread” the tape, the tape is unattached from the take-up reel and is physically placed back into the inside of a tape cartridge again. The cartridge may remain loaded in the tape drive even after the tape has been

## 12

unthreaded, e.g., waiting for another read and/or write request. However, in other instances, the tape cartridge may be unloaded from the tape drive upon the tape being unthreaded, e.g., as described above.

Magnetic tape is a sequential access medium. Thus, new data is written to the tape by appending the data at the end of previously written data. It follows that when data is recorded in a tape having only one partition, metadata (e.g., allocation information) is continuously appended to an end of the previously written data as it frequently updates and is accordingly rewritten to tape. As a result, the rearmost information is read when a tape is first mounted in order to access the most recent copy of the metadata corresponding to the tape. However, this introduces a considerable amount of delay in the process of mounting a given tape.

To overcome this delay caused by single partition tape mediums, the LTFS format includes a tape that is divided into two partitions, which include an index partition and a data partition. The index partition may be configured to record metadata (meta information), e.g., such as file allocation information (Index), while the data partition may be configured to record the body of the data, e.g., the data itself.

Looking to FIG. **9**, a magnetic tape **900** having an index partition **902** and a data partition **904** is illustrated according to one approach. As shown, data files and indexes are stored on the tape. The LTFS format allows for index information to be recorded in the index partition **902** at the beginning of tape **906**, as would be appreciated by one skilled in the art upon reading the present description.

As index information is updated, it preferably overwrites the previous version of the index information, thereby allowing the currently updated index information to be accessible at the beginning of tape in the index partition. According to the specific example illustrated in FIG. **9**, a most recent version of metadata Index **3** is recorded in the index partition **902** at the beginning of the tape **906**. Conversely, all three version of metadata Index **1**, Index **2**, Index **3** as well as data File A, File B, File C, File D are recorded in the data partition **904** of the tape. Although Index **1** and Index **2** are old (e.g., outdated) indexes, because information is written to tape by appending it to the end of the previously written data as described above, these old indexes Index **1**, Index **2** remain stored on the tape **900** in the data partition **904** without being overwritten.

The metadata may be updated in the index partition **902** and/or the data partition **904** the same or differently depending on the desired approach. According to some approaches, the metadata of the index and/or data partitions **902**, **904** may be updated in response to the tape being unmounted, e.g., such that the index may be read quickly from the index partition when that tape is mounted again. The metadata is preferably also written in the data partition **904** so the tape may be mounted using the metadata recorded in the data partition **904**, e.g., as a backup option.

According to one example, which is no way intended to limit the invention, LTFS LE may be used to provide the functionality of writing an index in the data partition when a user explicitly instructs the system to do so, or at a time designated by a predetermined period which may be set by the user, e.g., such that data loss in the event of sudden power stoppage can be mitigated.

Magnetic Recording Media and Fabrication of Layers Thereof

FIG. **10** depicts a partial cross-sectional view of the basic structure of a magnetic recording medium **1000**, not to scale, in accordance with various approaches described herein. As an option, the present magnetic recording medium **1000** may

be implemented in conjunction with features from any other approach listed herein, such as those described with reference to the other FIGS. Of course, however, such magnetic recording medium **1000** and others presented herein may be used in various applications and/or in permutations which may or may not be specifically described in the illustrative approaches listed herein. Further, the magnetic recording medium **1000** presented herein may be used in any desired environment. The magnetic recording medium **1000** in various permutations disclosed herein was developed to improve the stability and performance of tape storage media over the required environments for use and storage.

Except as otherwise described herein, the various layers of the magnetic recording medium **1000** may be of conventional construction, design and/or function. In various approaches, a new and novel layer may be used with conventional layers. In further approaches, multiple new and novel layers may be used together with other conventional layers.

Except as otherwise described herein, the various layers of the magnetic recording medium **1000** may be formed using conventional methods, especially where the respective layer is of conventional construction.

The magnetic recording medium **1000** is preferably a magnetic recording tape, but in other aspects is a different type of deformable media.

As shown in FIG. **10**, four basic layers are present in the magnetic recording medium **1000**. An optional backcoat **1002** is positioned along one side (lower side in the FIG.) of a substrate **1004**. An underlayer **1006** is positioned along another side (upper side in the FIG.) of the substrate **1004**. A recording layer **1008** is positioned above the underlayer **1006**. Additional layers of conventional construction may be present in the magnetic recording medium **1000**, in various approaches. For example, the backcoat may be eliminated and multiple layers deposited on both sides of the substrate to allow recording on both sides of the final tape.

#### Backcoat

The backcoat **1002** may or may not be present in the magnetic recording medium **1000**. The backcoat **1002** may be of conventional construction, design and function, and in some approaches may have a conventional composition including a conductive carbon black dispersed in a polymer binder system as commonly practiced in the industry for decades, though, again, any conventional backcoat material may be used. Preferably, the backcoat **1002** is constructed of a material that provides one or more of the following benefits: facilitate separation from another section of the tape would thereover on a spool, tribology improvement, dissipation of static electricity, etc. A preferred thickness of the backcoat **1002** is less than about 0.3 microns, preferably less than about 0.2 microns.

#### Substrate

The substrate **1004** is preferably of conventional construction, design and function. The substrate **1004** is typically the thickest layer. Illustrative materials for the substrate **1004** include polyethylene terephthalate (polyester or PET), polyethylene naphthalate (PEN), super-tensilised PEN, an aramid-like material (e.g., solubilized para-imide such as one sold under the trade name Mictrom™ sold by Toray Industries, Inc. having a place of business at Nihonbashi Mitsui Tower, 1-1, Nihonbashi-Muromachi, 2-chrome, Chuo-ku, Tokyo 103-8666, Japan), etc.

#### Underlayer

The underlayer **1006** provides one or more of the following functions in the structure: attenuation of magnetic signal passing through the recording layer, adhesion of the record-

ing layer to the substrate **1004**, etc. Accordingly, in most approaches described herein, the function of the underlayer **1006** is not to retain any memory of the writer flux, but rather to improve the write flux box coming from the write head element during writing to the recording layer **1008**. Moreover, any retained magnetic moment orientation from writing is preferably weak or non-existent so as to minimize noise during readback.

One very important attribute of the magnetic filled coating in the underlayer, according to various approaches, is to quickly absorb the stray field passing through the recording layer above during the very rapid magnetic switching encountered during writing. The ideal underlayer should have a very low remnant moment ( $M_r$ ) so that it retains no orientation after the write field passes through that volume of the underlayer.

In some approaches, the underlayer **1006** is of new and novel construction. The new and novel underlayer **1006** may be present in the medium **1000** with a conventional recording layer **1008** there above, in one aspect. In another aspect, the new and novel underlayer **1006** may be present in the medium **1000** with a new and novel recording layer **1008** there above. In other approaches, the underlayer **1006** is of conventional construction, and is present in the medium **1000** with a new and novel recording layer **1008** there above.

In various approaches, the underlayer **1006** has one or more of the following characteristics, and preferably all of the following characteristics: electrically conductive, weakly magnetic (a bulk magnetic strength in Oersted (Oe) that is less than 200 Oe, and preferably less than 100 Oe. Ideally, the underlayer is coated and calendared prior to formation of the recording layer **1008** thereon to improve the recording layer **1008** interface, as described in more detail below. In a preferred embodiment, the underlayer **1006** has about one tenth the coercivity in Oersteds) of the recording layer **1008** and low remnant magnetization enabling the underlayer **1006** to act as a magnetic field flux absorber without creating signal interference with the recording layer **1008** above it.

The electrically conductive characteristic is operative to reduce corrosion of magnetic heads operating on a tape. Particularly, when a tape is unwound, the separation between the recording layer generates a triboelectric potential and current, which in a dry environment can produce a static discharge, and in a humid environment produce an electro-chemical pathway for head corrosion. Both of these situations are undesirable for tape performance and durability, both believed to be a significant factor in head corrosion. The electrically conductive characteristic of the underlayer **1006** assists in dissipating the charge, e.g., by transporting the charge to a hub coupled to a ground, thereby minimizing charge traveling into the head and consequently lessening the risk of condensed liquid water forming a conductive path between the tape and head surface that provides a path for the electrochemical corrosion of the recording head structures.

The weakly magnetic characteristic reduces the amount of noise contributed by the magnetic fields emanating from the underlayer **1006** and improves the resolution of the written bits in the recording layer above the underlayer.

In approaches where the underlayer **1006** is of conventional construction and typically utilizes low coercivity and low moment particles in the micron size range. The coating is not optimized for a high loading of very small (nano scale) particles. The underlayer in some approaches is constructed with a weakly magnetic iron oxide using a conventional

polyester-polyurethane rubbery resin with a poly(vinyl acetate-vinyl alcohol-vinyl chloride) hard resin cured with a poly(isocyanate) as used in earlier tape product formats. However, such conventional coatings were not specifically designed or formulated to be an optimum underlayer for the signal recording layer above it in the final tape.

In preferred approaches, the underlayer **1006** includes a new formulation in which the underlayer **1006** includes particles **1010** which are weakly magnetic but are also electrically conductive and dispersed in a low-stress UV-cured matrix providing good adhesion to the substrate and providing mechanical stability and stress relief to the very thin recording layer above it.

The underlayer **1006** does not need to have a narrow distribution of nanoparticle sizes, in various approaches, though use of small particles improves the surface roughness presented to the recording layer when the recording layer is being applied. Using the novel fabrication processes described herein, the underlayer **1006** is not attacked (swollen by the recording layer during application of the recording layer thereon).

In preferred approaches, the underlayer **1006** includes a new formulation in which the underlayer **1006** includes encapsulated nanoparticles **1010** each comprising at least one magnetic nanoparticle **1012**, and preferably only one magnetic nanoparticle **1012**, encapsulated by an aromatic polymer **1014**. A polymeric binder **1016** binds the encapsulated nanoparticles in the underlayer **1006**.

An average concentration of the encapsulated nanoparticles in the underlayer **1006** is preferably at least about 35 vol %, e.g., 40 vol %, 45 vol %, 50 vol %, 55 vol %, 60 vol %, greater than about 60 vol %, in a range of about 40-75 vol %, in a range of about 45-75 vol %, in a range of about 50-75 vol %, in a range of about 35-50 vol %, in a range of about 40-60 vol %, or any other sub-range within the aforementioned ranges. Ideally, the average concentration of the encapsulated nanoparticles does not exceed the critical pigment volume concentration (CPVC) at which the coating would lose its mechanical integrity and no longer function as a viable, durable coating. For nanoparticle filled coatings, a very high surface area can reduce the CPVC dramatically unless a novel encapsulation of the nanoparticles and binder design is implemented to allow a higher CPVC. The CPVC may be determined using Dynamic Mechanical Analysis (DMA) of free films of the coating for a series of coatings with increasing vol % of the filler. Conventional DMA techniques may be used on the novel formulations described herein. The CPVC is determined at the vol % at which the tensile storage modulus ( $E'$ ) reaches its maximum value. FIG. **11** depicts a CPVC DMA plot **1100** for various vol % of pigment in an underlayer, according to various approaches. Such plot **1100** is exemplary of plot(s) which may be generated by one skilled in the art following the teachings herein and using conventional DMA plotting techniques, and without resorting to undue experimentation.

The magnetic nanoparticles preferably include a weakly ferrimagnetic material. By "weakly ferrimagnetic" what is meant is that the magnetic nanoparticles do not have a high coercivity ( $H_c$ ) or magnetic moment ( $M_r$ ), but rather have an average magnetic field strength that contributes a minimal signal during reading of the overlaying recording layer. The final coating ideally presents no detectable noise signal contribution to the observed response for the written bits in the data storage layer.

In preferred approaches, the magnetic nanoparticles have a coercivity ( $H_c$ ) of less than about 200 Oe, more preferably less than 100 Oe, and greater than 50 Oe. An exemplary

range of the field strength of the magnetic nanoparticles is 50-200 Oe. The magnetic nanoparticles are also preferably characterized by a low remnant moment, e.g., <12 emu/g.

A preferred material for the magnetic nanoparticles is a chromium dioxide, which is weakly magnetic, electrically conductive, and very hard. In other approaches, the magnetic nanoparticles include one or more of: magnetic metal particles having an oxidized outer surface or oxide thereon (at the cost of conductivity) such as cobalt, nickel or iron, and alloys thereof.

An average diameter of the magnetic nanoparticles is preferably in a range of 2 nanometers (nm) to 20 nm, more preferably 4 nm to 10 nm, depending on the material, though the average diameter could be higher or lower than this range in some approaches. One consideration about average diameter is that the smaller the size, the harder it may be for the binder to properly hold the pigments in the coating matrix. Accordingly, the average diameter of the magnetic nanoparticles should be selected to maintain the critical pigment volume in an acceptable range. If the average diameter is too small, insufficient binder may be present between adjacent particles, making the material brittle and susceptible to breakage. If the particles are too large, the interface between the underlayer **1006** and recording layer **1008** loses the desired smooth characteristic described herein.

In preferred approaches, the magnetic nanoparticles present in the underlayer are weakly magnetic and electrically conductive and are formulated to produce a dried coating with negligible or no swelling by the solvent used to apply the recording layer. The use of nanoparticles in the underlayer is preferred to use of larger particles so as to allow a smoother interface with the recording layer.

The encapsulated nanoparticles in various preferred implementations may have a broad size distribution so long as the resulting dried film does not exceed the critical pigment volume concentration.

Preferably, the majority of the particles in the underlayer **1006** are coated with sufficient binder so as to achieve a cohesive and stable coating with a minimal number of coated clusters of particles or aggregates. The ideal coating would have no clusters or aggregates in the final coating such that close to 100% of the particles are completely dispersed in the binder matrix as individual particles. Good dispersion of the particles into the matrix with minimal orientation of the particles further reduces the noise contribution of the underlayer to the recorded signal in the recording layer.

Also preferably, the encapsulated nanoparticles are not well aligned with each other, e.g., are randomly oriented in the underlayer **1006**. This further improves the performance of the underlayer by reducing formation of ordered magnetic regions within the underlayer **1006** which reduces the noise produced in the underlayer **1006**. Nonetheless, while it is desirable to generate a monodisperse non-aggregated dispersion of encapsulated particles for the coating preparation, this is not necessary for the underlayer, since the mechanical properties are more important than magnetic signal performance.

The aromatic polymer encapsulating the magnetic nanoparticles may be and/or include any of many different aromatic polymers, as long as the aromatic polymer encapsulates at least about 80% of the surface of the magnetic nanoparticle, preferably at least about 90% of the surface of the magnetic nanoparticle, and ideally approximately 100% of the magnetic nanoparticle in the underlayer **1006**.

Accordingly, the aromatic polymer forms at least a partial shell, and preferably a full shell, around the magnetic nanoparticles.

The layer encapsulating the nanoparticles can be as thin as a molecular monolayer, e.g., less than 0.4 nm, but a more robust layer is achieved at about 1-2 nm thick. As the layer becomes thicker the packing of the nanoparticles into the coating decreases. This is not as critical in the underlayer as it is in the recording layer.

An average thickness of the aromatic polymer encapsulating the magnetic nanoparticles is preferably in a range of about 0.5 nm to about 8 nm, e.g., 1-4 nm, 3-5 nm, 4-5 nm, 4-7 nm, 5-7 nm, etc. but could be slightly higher or lower than these ranges. Thicknesses used herein generally refer to deposition thickness on the underlying structure, unless otherwise noted.

Aromatic polymers are preferred as the encapsulating layer, because the aromatic ring structure(s) that encapsulates the surface of the magnetic nanoparticle. Aromatic rings have a very beneficial behavior, particularly with chemically reactive metal oxides such as chromium oxide, due to the unique characteristic of aromaticity in such molecules which offers improved stability and some magnetic shielding at the surface of the magnetic nanoparticles if properly aligned with the magnetic axes of the magnetic nanoparticles. For example, the aromatic ring structures can act as a magnetic field modifier due to their unique molecular electronic structure and ability to moderate an external magnetic field.

Aromatic polymers also provide magnetic shielding at the surface of the pigment, and help isolate the magnetic nanoparticles from other particles to improve the independent switching of the encapsulated nanoparticles, resulting in higher bit resolution.

A preferred aromatic polymer is a carbamate. A preferred example of an aromatic molecule known to react with chromium dioxide particles to effectively encapsulate and isolate the particles from its neighbors in a close packed matrix is methylene bis diphenyl carbamate. Ideally, the encapsulating polymer is constructed from methylene bis diphenyl carbamate with a functional acrylic polyester as the ester segment for the aromatic carbamate when used with nanoparticles of chromium dioxide. Upon UV irradiation, polymerization on the surface of the particle can proceed to form the encapsulating polymer film layer.

For use with chromium dioxide magnetic nanoparticles in particular, the aromatic polymer is preferably an aliphatic substituted aromatic, e.g., having an oxidizable portion that reacts with chromium, thereby assisting in adsorption of the aromatic polymer to the chromium dioxide microparticle. The benzylic carbon of the diphenyl methane dicarbamate is known to be oxidized efficiently by chromium dioxide to tightly bind the resulting diphenyl ketone to the particle surface.

In other approaches, the aromatic polymer includes reactive functional substituent such as amines, alcohols, carboxylic acids or nitrile groups. An example is cinnamic which is present as a copolymer with styrene to form a bound polymer layer on the nanoparticle surface.

In yet other approaches, the aromatic polymer includes one or more repeating units with substituents capable of chemical adsorption and/or bonding to the particle surface such as amines, a carboxylic acid such as cinnamic acid, and other functional aromatics that will bind with the surface of the magnetic nanoparticle being used.

In an alternative implementation, the encapsulating layer of the encapsulated microparticles is not of a fully aromatic

polymer but may be a copolymer such as a polyester polyurethane or acrylic modified polyurethane. Examples include aliphatic polymers of known type, non-aromatic polymers of known type, etc.

The polymeric binder binding the encapsulated nanoparticles together may be and/or include various types of binder material. In preferred approaches, the binder includes an acrylic polymer, e.g., a polymer of acrylic acid or an acrylate, and preferably a functional acrylic polymer. Illustrative acrylic polymers suitable for use as a binder in various approaches include components such as methyl methacrylate, acrylic acid, and others. In general, preferred polymeric binders are those with a number average molecular weight of less than about 2400, and preferably less than about 1200.

In a preferred implementation, the polymeric binder has UV curable functionality to enable binding to the encapsulating layer of the encapsulated microparticles. This functionality can be provided by acrylate groups, vinyl, etc.

In some approaches, the binder includes a vinyl chloride, vinyl acetate-vinyl alcohol copolymers. In yet other approaches, the binder includes polyester or polyether polyurethanes. For the nanoparticle filled coatings the polymers will be much lower molecular weight (size) than previously employed materials. Typically, the useful polymers are less than 20 repeat units in length prior to UV cure.

The relative amounts of encapsulated nanoparticles to binder in the underlayer **1006** should be in a range that is not above the critical pigment volume concentration (CPVC). One skilled in the art, once armed with the novel formulations described herein, would be able to calculate the CPVC using known techniques based on the characteristics of the materials used, such as binder used, particle surface area, etc. A general rule of thumb is less than about 50 vol % pigment (encapsulated nanoparticles) in the underlayer **1006**, so that structural integrity of the underlayer **1006** is maintained, along with other functions of the underlayer **1006** such as structurally stabilizing the magnetic layer, enhancing durability of the tape, and providing adhesion of the recording layer **1008**. The pigment loading is preferably high enough to provide adequate mechanical integrity as measured with DMA will preserving enough electrical conductivity to mitigate undesirable triboelectric properties.

Additional materials may be present in the underlayer **1006**, such as mobile lubricants and/or stabilizers used for dispersion stabilization prior to application and cure.

The resulting underlayer **1006** is preferably characterized by a weakly magnetic, electrically conductive, encapsulated nanoparticle dispersion in a tightly bound binder to the pigment (encapsulated nanoparticles) so as to achieve a dried coating with an onset glass transition temperature  $T_g$  in the Tensile Storage Modulus ( $E'$ ) vs. temperature plot from 0° centigrade (C.) to 60° C. The  $T_g$  should be higher than 35° C., preferably in excess of about 45° C., and an absolute value for  $E'$  measured at 10 Hz via DMA at 20° C. of at least about 6 gigapascals (GPa) up to about 16 GPa or slightly higher, e.g., about 8 GPa, about 10 GPa, about 11 GPa, 12 GPa, about 15 GPa, about 16 GPa. The normal operating range for tape, in most approaches, is in the range of 0° C. to 60° C., but could be higher or lower.

Binders used in conventional magnetic recording tapes result in an underlayer **1006** having a glass transition temperature of 20-30° C. This is too soft, resulting in the underlayer **1006** being too pliable during use to provide a stable and consistent recording medium. However, the underlayer **1006** should be sufficiently elastic to remain tough and durable during use and storage. Accordingly,

preferred embodiments result in an underlayer **1006** that has an onset Tg as determined by a DMA plot of the E' vs temperature in excess of about 35° C., with the preferred onset Tg of a very broad response that remains in the elastic regime at 10 Hz to at least 50° C.

An average thickness of the underlayer **1006** is less than 1 micron and preferably less than about 0.6 microns. Lower thicknesses are preferred to allow more tape to be wound into the fixed volume of a given tape cartridge.

In preferred approaches, no wear particles are present in the underlayer **1006**, and ideally, no wear particles are present in the product at all. Wear particles, conventionally added for purposes of cleaning the tape head and/or reducing stiction, have been found to constitute an increasingly intolerable defect and source of damage to the shrinking read and write structures in current and future recording heads. However, in other approaches, wear particles may be present in the underlayer **1006**.

The underlayer **1006** is preferably applied to the substrate **1004**, at least partially dried, and cured prior to application of the magnetic recording layer **1008** to minimize interlayer turbidity. Accordingly, in preferred approaches, the recording layer **1008** is substantially not intermixed with the underlayer **1006** (and vice versa). This feature overcomes a longstanding problem in magnetic recording tape products.

Referring to FIG. 12, there is shown a TEM image of a cross section of a conventional recording tape **1200**. As shown, the interface between the recording layer and the underlying underlayer is clearly defined. The light particles in the recording layer are barium ferrite particles. As shown, the barium ferrite particles are not monodisperse, nor tightly packed in the recording layer. Moreover, voids are present where there are no particles. In addition, the interface between the recording layer and underlayer is quite rough. Ideally, magnetic fields would pass from a writer perfectly perpendicular through the recording layer. Unfortunately, magnetic fields expand, or curve, upon leaving writer, with the curvature being more pronounced the farther it is from the pole tip of the writer. The voids, undulating interface between the recording layer and underlayer, and nonuniform dispersion of the magnetic particles all compound the effects of the expanding writer field. Where a transition is written (e.g., write field directed down, then up as the tape moves past the writer), and the field is expanding, say 10-20% as it passes through the recording layer, the transition is not sharp, reducing the resolution of the tape. During readback, the transition is noisy because it is not sharp. A 1 dB improvement in the signal to noise ratio (SNR) during readback is a significant achievement. The inventor believes an improvement of up to 5 or 6 dB in the signal to noise ratio (SNR) during readback can be achieved using the new and novel recording layer described herein formed upon a cured underlayer whereby interlayer turbidity is minimized.

In preferred approaches, the upper surface of the underlayer is substantially flat, with a modulation of less than about 25% of the thickness of the interfacial boundary as imaged in the TEM cross section of the final tape coating, preferably less than about 5%, e.g., like the upper surface of the recording layer shown in FIG. 12.

#### Process for Fabricating Underlayer

A method for fabricating the underlayer **1006**, e.g., of a magnetic recording medium, in accordance with various approaches, is presented below. As an option, the present method may be implemented to fabricate underlayers **1006** such as those described above. Of course, however, this method and others presented herein may be used to form underlayers **1006** which may or may not be related to the

illustrative aspects listed herein. Further, the methods presented herein may be carried out in any desired environment. Moreover, more or less operations than those described below may be included in the method, according to various approaches. It should also be noted that any of the aforementioned features may be used in any of the approaches described in accordance with the various methods.

The method generally includes forming an underlayer **1006** that has encapsulated nanoparticles each comprising at least one magnetic nanoparticle encapsulated by an aromatic polymer, and a polymeric binder binding the encapsulated nanoparticles.

Encapsulated nanoparticles may be purchased, or fabricated. For example, in some approaches, commercially available encapsulated nanoparticles usable for medical imaging and drug delivery applications may be used.

In one approach, forming the underlayer **1006** includes mixing the polymeric binder with the encapsulated nanoparticles and a solvent (solvent system) to form a mixture. The relative amounts of encapsulated nanoparticles and binder are preferably selected to provide characteristics listed in the previous section. For example, the mixing includes ultrasonically dispersing the encapsulated nanoparticles into the polymeric binder and solvent, thereby creating a radiation-curable emulsion in the solvent.

Conventional coating methods would require formulation to achieve a useful viscosity and likely require much higher molecule weight binders than would be optimal for the target design for the present advanced tape construction. As a result, what are described herein are examples of formulations not suitable for conventional coating. All of the examples are best applied to the substrate as a sprayed-on aerosol coating, though other coating methods are contemplated.

In general, the solvent used herein should provide one or more, and preferably all, of the following characteristics: the solvent causes the polymeric binder to swell, but allows the polymers to collapse around the pigment rather than shrinking during drying. The solvent causes the chain of the polymeric binder to uncoil and move toward its theta condition (minimum free volume).

The layer is most stable when the polymeric binder is in theta condition, and it is at this point where the curing should occur. UV curing is preferred when the polymeric binder is close to its theta condition due to the speed at which curing occurs.

One of the solvent components should be a good solvent for the binder additive, and helps suspend the polymer encapsulated magnetic particles. The second solvent may be a non-solvent for the polymeric binder. As the 'good' solvent phase evaporates, the remaining coating moves closer to a non-solvent dominated coalescing coating. The second solvent-rich coating thus passes through a point in the drying process in which the binder and encapsulated magnetic particles are about at their minimum free volume or theta conditions. This produces a minimal residual stress in the final, dried coating. This in turn eliminates curl and cupping in the final tape.

A preferred solvent is a water and tetrahydrofuran (THF) solvent system in relative concentrations that render the solvent system almost completely azeotropic. This solvent system is preferred for use with acrylic polymer binders, as it dries well, is environmentally friendly, takes less energy, and is less sensitive to combustion or explosion as an azeotrope. The THF/water solvent is also preferred because the THF leaves first while drying, followed by the water, which assists in maintaining the binder toward theta condi-

tion. Particularly, the THF leaves first due to its higher volatility than water. Exit of the organic solvent first allows the coalescence of the film to collapse and reduce the stress. Water then dominates the solvent interface, thereby allowing the polymer to approach theta conditions.

Only a slight increase in the fraction of water over the azeotropic mixture concentrations of (e.g., 6.7 mass percent) is needed to provide optimum coating drying. The results in solvent mixture in the range of 7-8% water in 92-93% THF drying at 64° C. This lower drying temperature has the added benefit of reducing operating costs compared to current magnetic tape coating processes.

The resulting mixture (pigment+solvent) is applied onto a structure, such as the substrate **1004**. Any suitable technique may be used to apply the mixture. Where the mixture of pigment and solvent form an emulsion, a preferred technique is spray coating, which provides fast, uniform application without streaks typical of brush coating or chunks typical of blade coating. Other application techniques include blade coating, slot-die coating, use of gravure rolls, etc.

In another approach, forming the underlayer **1006** includes mixing the polymeric binder with the encapsulated nanoparticles to form a micro-suspension without the addition of dispersants or other additives to create a stable dispersion.

The applied mixture is dried to remove at least some of the solvent, or substantially fully dried. For example, the applied mixture may be dried so the more volatile organic solvent (e.g., THF) is removed, thereby increasing the non-solvent content in the drying film. The polymeric binder collapses between the encapsulated microparticles as the solvent is removed during the drying. For example, in one aspect in which the binder is hydrophobic, the last solvent to leave the applied mixture is water, a non-solvent for the binder, which thus forces the hydrophobic binder to collapse onto the pigments. This also minimizes the residual stress in the dry coating, thereby preventing such things as tape curling. The drying is preferably performed using forced air under low temperature (less than about 75° C.) conditions.

The partially dried coating which will eventually provide the underlayer for the magnetic recording layer may be cured using, e.g., a thermal-induced chemical reaction to cure the two layers, a radiation-induced chemical reaction to cure the two layers, etc. For example, UV light or other known radiation exposure is applied to cause crosslinking of the polymeric binder. If proper solvent selection is employed for both coatings, the cure step results in minimal stress between the two layers and results in a stable (flat) coating.

In the case of thermal-induced cure, a chemical reaction may be used to reduce solvent swelling in the coating as well as improve the mechanical properties of the cured coating. Chemical cure in a dry film is slow and inefficient in achieving the desired uniformity of a cured highly filled coating. The preferred approach is to use radiation-induced chemical cure. Fortunately, all current and future magnetic recording layers employed for tape applications are now thin enough to allow efficient movement of light through the coating and effect chemical reactions within the binder-rich regions which are the target of such cure reactions. It is well known that ultraviolet (UV) radiation can activate the formation of free radicals which can attack unsaturated carbon bonds such as olefins, vinyls and acrylates to initiate polymerization of these reactive species to form more rigid molecular structures. UV curing is also preferred, as the

underlayer **1006** may also bind to some substrates **1004** during free radical formation, thereby improving durability of the tape.

After curing the underlayer **1006**, a magnetic recording layer **1008** is formed on or above the underlayer **1006**. By drying and curing the underlayer **1006** before forming the magnetic recording layer **1008** of any type thereon, inter-layer turbidity at the interface between the underlayer and the recording layer is minimized. This overcomes a problem that has been prevalent in conventional magnetic recording tape manufacture, resulting in a limit on the achievable areal recording density of the tape.

In one exemplary approach, nanoparticles of a weakly magnetic material (chromium dioxide) are coated with an aromatic polymer shell (methylene bis diphenyl carbamate with a functional acrylic polyester as the ester segment for the aromatic carbamate) and bound together with a functional acrylic polymer. A formulation of the foregoing materials is dispersed using ultrasonic dispersion methods into an ultraviolet (UV) curable emulsion in a tetrahydrofuran (THF) and water solvent system, applied above the substrate **1004**, dried, and cured. The dried coating has the pigment encapsulated with the aromatic glassy polymer such that the matrix is highly filled with the magnetic and electrically conductive pigment to over 40% while maintaining an elastic, rubbery interparticle matrix formed from the polyester-acrylate regions of the carbamate binder.

Process for Fabricating Encapsulated Magnetic Nanoparticles

In various approaches, the base magnetic nanoparticles, to be encapsulated later using any of the novel processes disclosed herein, are prepared using known techniques, e.g., milling. In other approaches, the base magnetic particles are obtained in ready-to-use form and encapsulated using any of the novel processes disclosed herein.

The formation of encapsulated magnetic nanoparticles may be performed using various techniques. Prior approaches to encapsulate magnetic nanoparticles have proven unsuccessful. Rather than attempt to maintain isolation of the encapsulated nanoparticle precursors (not yet converted to the final magnetic state by high heat conversion), in preferred approaches, the magnetic nanoparticles are mixed with an organic solvent in which an aromatic dispersant is present. Absorption of the aromatic species onto the nanoparticles allows a stable suspension of the particles in the initial solvent, such as toluene which is a good solvent for many appropriate aromatic dispersants. The mixture is heated with ultrasonic dispersion energy applied to maintain the suspension. A high boiling aromatic hydrocarbon such as anthracene, phenanthrene, pyrene, etc. is added to the approximate volume of toluene prior to distillation. The mixture is heated above the boiling point of toluene and the toluene distilled away leaving a molten suspension of the dispersed nanoparticles in the fully aromatic polyaromatic melt, such as molten phenanthrene, which melts above 380° C.

In one illustrative approach, the mixture is heated in a pressure vessel to allow the temperature to be raised to 400° C. and held for four to six hours. The iron nanoparticles are converted to the magnetic epsilon form of iron oxide. In this process the magnetic particles remain encased in a fully aromatic shell.

The mixture is then cooled to room temperature before processing to extract the encapsulated particles is carried out. Once cooled to room temperature, the waxy solid with the dispersed nanoparticles is dissolved in a solvent such as toluene to once again obtain a dispersion of the nanopar-

ticles in the mixed aromatic solvents. To this is now added sufficient chloroform or the like to allow the aromatic layer to separate and be decanted from the particles suspended in chloroform.

Dry particles can be recovered by distillation of the chloroform or a suspension maintained by solvent exchange into water to form an emulsion if the aromatic encapsulation layer is modified so as to have sufficient residual polar functionality so that allows stable dispersion into water.

#### Recording Layer

In some approaches, the recording layer **1008** is of new and novel construction. The new and novel recording layer **1008** may be present in the medium **1000** with a conventional underlayer **1006** therebelow, in one aspect. In another aspect, the new and novel recording layer **1008** may be present in the medium **1000** with a new and novel underlayer **1006** therebelow. In other approaches, the recording layer **1008** is of conventional construction, and is present in the medium **1000** with a new and novel underlayer **1006** therebelow.

In approaches where the recording layer **1008** is of conventional construction, a dispersion of weakly magnetic particles dispersed in a binder system which does not attempt to encapsulate the particles in a glassy encapsulating layer prior to dispersion may be used as the flux dissipation layer as has been practiced in the construction of current tape media for over a decade. These underlayers may or may not have additional particles added for conductivity or abrasive strength improvement.

In preferred approaches, the recording layer **1008** includes a new formulation in which the recording layer **1008** includes encapsulated nanoparticles **1018** each comprising at least one magnetic nanoparticle **1020**, and preferably only a single magnetic nanoparticle **1020**, encapsulated by an encapsulating layer **1022**, and a polymeric binder **1024** binding the encapsulated nanoparticles. In general, the magnetic strength of the magnetic nanoparticles in the recording layer **1008** is significantly greater than the magnetic strength of nanoparticles in the underlayer **1006**, if present.

An average concentration of the encapsulated nanoparticles in the recording layer **1008** is preferably at least about 35% by weight (wt %), e.g., about 45-50% wt %, in a range of about 35-50 wt %, preferably in a range of about 46-50 wt %, or any other sub-range within the aforementioned ranges.

The magnetic nanoparticles in the encapsulated nanoparticles of the recording layer **1008** may be constructed of any magnetic material suitable for the intended application, such as magnetic recording. Moreover, magnetic materials usable in magnetic imaging may be used in the magnetic nanoparticles in some approaches. In various approaches, the magnetic nanoparticles include at least one magnetic material selected from the group consisting of: alloys and/or oxides of nickel, cobalt, and iron including mixed compounds and crystals using combinations of nickel, cobalt, and iron such as: iron-barium, NiFe, barium ferrite, and cobalt platinum.

It should be noted that the approach described herein is applicable to other nanoparticles currently not typically useful for tape storage layers such as MnAl and even non-magnetic dispersions which could benefit from improved control of the coating integrity such as SiC and SiO<sub>2</sub> dispersions useful in sand papers and other abrasives. Accordingly, any known type of magnetic nanoparticle may be used in various approaches.

In preferred approaches, the magnetic nanoparticles include at least one magnetic material selected from the

group consisting of: Co<sub>3</sub>O<sub>4</sub>, CoFe, Fe<sub>3</sub>O<sub>4</sub>, alpha iron oxide ( $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>), epsilon iron oxide ( $\epsilon$ -Fe<sub>2</sub>O<sub>3</sub>), and Co(fcc). In other approaches, the magnetic nanoparticles may include manganese aluminum alloys, oxides of magnetic metals, and pinel ferrites.

An average diameter of the magnetic nanoparticles in the recording layer **1008** is preferably in a range of about 2 nm to about 20 nm, preferably in a range of about 2 nm to about 10 nm, especially for the epsilon iron oxide particles. The average diameter could be higher or lower than this range in depending on the size at which the magnetic nanoparticle loses its remanence and becomes superparamagnetic. In general, a smaller average diameter is better for purposes of increasing bit resolution.

Preferably, the encapsulated nanoparticles used in the recording layer have the same composition, crystal structure and morphology as well as a very narrow particle size range to optimize the final recording layer response to an applied external field during data writing. In preferred approaches, greater than about 80% of the encapsulated nanoparticles have only a single magnetic nanoparticle therein, more preferably greater than about 90, even more preferably greater than about 98%, and ideally at least about 100% of the encapsulated nanoparticles have only a single magnetic nanoparticle therein.

The aromatic polymer encapsulating the magnetic nanoparticles may be and/or include any of many different aromatic polymers, as long as the aromatic polymer encapsulates at least about 75% of the surface of the magnetic nanoparticle, preferably at least about 90% of the surface of the magnetic nanoparticle, and ideally approximately 100% of the magnetic nanoparticle in the underlayer **1006** and especially for optimization of the magnetic nanoparticles in the recording layer. In the recording layer, the efficiency of the particle encapsulation should be as close to 100% as can be obtained by a viable process used to construct large quantities in practice. Accordingly, the aromatic polymer forms at least a partial shell, and preferably a full shell, around the magnetic nanoparticles. An average thickness of the aromatic polymer encapsulating the magnetic nanoparticles is preferably less than 1 nm in the final recording layer **1008**. Preferably, the average thickness of the aromatic polymer shell is in a range of about 0.5 nm to about 1 nm, e.g., 0.5-0.75 nm, 0.6-0.8 nm, 0.7-1 nm, 0.8-1 nm, etc. but could be slightly higher or lower than these ranges. In some instances, clusters or aggregates of partially coated nanoparticles may be formed during the encapsulating process which may persist through the formulation process into the final coating. So long as these clusters and aggregates are not a significant fraction of the coating (e.g., less than 10% by volume) and smaller than the final coating thickness so as not to impart surface roughness and defects (e.g., <60% the thickness of the final dried coating in diameter) the presence of clusters and aggregates should not be limiting on the desired functionality of the layer.

In embodiments where the encapsulated nanoparticles are pyrolyzed, the average thickness of the resulting carbon shell is in a range of about 0.05 nm to about 1 nm.

Such thin shells improve magnetic particle packing density in the recording layer **1008**, and thus enable higher recorded bit resolution.

Aromatic structures are preferred as the encapsulating layer for the isolation of magnetic nanoparticles due to their unique electronic properties which provide some weak but significant separation of each nanoparticle from the magnetic field coupling them with their near neighbors in the final close-packed dry coating.

The aromatic polymer preferably includes functional groups that have an affinity to adhesion to iron oxide where iron magnetic nanoparticles are used. Illustrative functional groups include carboxylate functional groups, nitrile functional groups, and others.

A preferred aromatic polymer is a radiation curable substituted aromatic polymer. In another approach, the aromatic polymer is a styrene, such as polystyrene. Ideally, the aromatic polymer is polystyrene with a copolymer which has a rubbery polymer chain in the para-position on the styrene monomer. Preferably, the encapsulating layer includes a polyaromatic film.

In other approaches, the aromatic polymer is one that is a known precursor usable for creating graphite, carbon fiber, carbon nanotubes, etc. Accordingly, the encapsulating layer may be a graphite-like dominated continuous film.

The polymeric binder binding the encapsulated nanoparticles together may be and/or include various types of binder material.

Contemplated approaches attempted to incorporate encapsulated magnetic nanoparticles into conventional binder systems, but it was found that such approaches result in recording layers that have far more noise and much poorer signal performance than would be predicted from the assumption that the particles are smaller and more packed into an oriented film. While the reason for such poor performance in approaches using conventional binder systems is not completely understood, the inventor has found that the novel techniques described herein result in a new recording layer that exhibits excellent recording performance, far superior to said approaches using conventional binder systems.

In preferred approaches, the binder includes an acrylic polymer, e.g., a polymer of acrylic acid or an acrylate, and preferably a functional acrylic polymer. In particularly preferred approaches, the polymeric binder includes a radiation curable rubbery acrylic polymer. Illustrative acrylic polymers suitable for use as a binder in various approaches include acrylic terminated polyester, and those that include components such as methyl methacrylate, acrylic acid, and others. For example, the binder may include an acrylic terminated aliphatic polyester or aliphatic polyether polymer. In general, preferred polymeric binders are those with a number average molecular weight of less than about 2400, and preferably less than about 1200.

The binder used in the recording layer **1008** may be the same as, or different than, the binder used in the underlayer **1006**, in various approaches.

The recording layer **1008** should be flexible (rubbery) over the in-use operating temperature range, while providing tear resistance and shock resistance. Accordingly, preferred embodiments result in a recording layer **1008** that has a glass transition temperature in excess of about 35° C., preferably in excess of about 45° C., and ideally at least about 50° C. This can be achieved via selection of the binder.

Additional materials may be present in the recording layer **1008**, such as lubricants. However, one benefit of various approaches disclosed herein is that they allow the elimination of conventional additives such as wear particles to the recording layer.

An average thickness of the recording layer **1008** as measured perpendicular to the plane of formation thereof is less than about 0.2 microns, and preferably less than about 0.1 micron. One benefit of this thickness of recording layer **1008** is that the UV light is able to reach all portions of the recording layer **1008** even with the pigment therein, thereby ensuring a fast, consistent cure throughout the layer. Con-

ventional recording layers, being thicker, were unable to be UV cured, and therefore relied upon other types of curing that were not as fast. Accordingly, as the conventional tape was formed, curing continued as the tape was wound onto a spool. However, winding the tape onto the spool created tensions and stresses (e.g., radial compression) throughout the tape, resulting changes in the mechanical characteristics of the tape that varied from the tape at the inside of the hub to the tape at the outside of the hub.

Where the recording layer **1008** is formed directly on an underlayer **1006**, the recording layer **1008** is preferably applied after curing of the underlayer **1006** to minimize interlayer turbidity. Accordingly, in preferred approaches, the recording layer **1008** is substantially not intermixed with the underlayer **1006** (and vice versa).

Preferably, the underlayer **1006** has a bulk magnetic field strength in Oe that is less than 200 Oe, and preferably less than 100 Oe. The underlayer **1006** may have similar construction and/or characteristics as the underlayers disclosed elsewhere herein.

In some aspects, lubricant molecules **1030** are coupled to a surface of the recording layer **1008**. The lubricant molecules may be bound to the surface, embedded in the surface, or both. Preferably, the amount of the lubricant molecules along the surface of the recording layer **1008** is less than an amount that would form a continuous lubricant film along the surface of the recording layer **1008**.

In preferred approaches, no wear particles are present in the recording layer **1008**, and ideally, no wear particles are present in the product at all. However, in other approaches, wear particles may be present in the recording layer **1008** and/or pass therethrough from an underlayer **1006**. It is expected that the foregoing mechanical design of the recording layer **1008** with an electrically conductive underlayer **1006** will achieve the desired low friction and head corrosion properties of the tape surface without the need for the inclusion of wear particles, which constitute an increasingly intolerable defect and source of damage to the shrinking read and write structures in current and future recording heads.

#### Process for Fabricating Recording layer

A method for fabricating the recording layer **1008**, e.g., of a magnetic recording medium, in accordance with various approaches, is presented below. As an option, the present method may be implemented to fabricate recording layers **1008** such as those described above. Of course, however, this method and others presented herein may be used to form recording layers **1008** which may or may not be related to the illustrative aspects listed herein. Further, the methods presented herein may be carried out in any desired environment. Moreover, more or less operations than those described below may be included in the method, according to various approaches. It should also be noted that any of the aforementioned features may be used in any of the approaches described in accordance with the various methods.

The method generally includes forming a magnetic recording layer **1008** having encapsulated nanoparticles each comprising at least one magnetic nanoparticle encapsulated by an aromatic polymer, and a polymeric binder binding the encapsulated nanoparticles.

In one approach, forming the recording layer **1008** includes heating the magnetic nanoparticles and aromatic polymer to a temperature that results in a suspension of the magnetic nanoparticles in the aromatic polymer. In general, for most aromatic polymers, the temperature is in a range of

about 200 degrees Celsius to about 538 degrees Celsius, depending on the aromatic polymer used.

Where the aromatic polymer has a simple aromatic structure, a temperature of less than 200 degrees Celsius may be used. The relative amounts of magnetic nanoparticles and aromatic polymer in the suspension are preferably selected to provide characteristics listed in the previous section, as well as to avoid creating clusters of nanoparticles.

An organic solvent may be mixed with the nanoparticles and aromatic polymer to create a suspension that prevents clustering and sintering of the nanoparticles. Such solvents may include molten aromatic solvents such as phenanthrene. Preferably, the solvent is one that does not result in oxidative reactions with the magnetic nanoparticles. Toluene or the like may also be added to shift the mixture more toward an emulsion.

In some approaches, the encapsulated particles are pyrolyzed, resulting in a magnetic nanoparticle that is encapsulated in a carbon shell.

The warm suspension of magnetic nanoparticles and aromatic polymer is mixed with a polymeric binder and a solvent to form a mixture. Ultrasonic dispersion is preferably used to create an emulsion. This technique of encapsulated nanoparticle synthesis and polymer encapsulation beneficially eliminates the need for milling and redispersion from aggregated clusters of particles, as is typical in conventional fabrication techniques.

In general, the solvent mixture should provide one or more, and preferably all, of the following characteristics: the most volatile solvent (first to leave during drying) causes the polymeric binder to swell, the second or last solvent to leave during drying is ideally a poor solvent for the binder so that during drying the solution passes through theta conditions for that binder and forces the binder to collapse around the pigment, rather than shrinking during drying which results in undesirable stress in the final coating. The last solvent to leave during drying, being a non-solvent for the binder, forces the swollen chains to coil into their minimum free volume state, referred to as the theta condition, as it passes from being well solvated by the first solvent to being encased in a non-solvent rich environment during drying. The layer is most stable when the polymeric binder is in theta condition, and it is at this point where the curing should occur. UV curing is preferred when the polymeric binder is close to its theta condition due to the speed at which curing occurs.

A preferred solvent is a water and THF solvent system in relative concentrations that render the solvent system predominately azeotropic with a slight excess of water to force the final drying coating to pass through theta conditions during drying. The THF leaves first due to its higher volatility than water. Exit of the organic solvent first allows the coalescence of the film to collapse and reduce the stress. Water then dominates the solvent interface, thereby allowing the polymer to approach theta conditions.

In other approaches, the system may be dominated by water such that the coating is a true emulsion, with the absorbed binder acting as an emulsifier as well as providing the rubber phase resin in the final coating. In further approaches, the useful solvents may include mixtures of volatile polar organics with higher boiling non-solvents for the binders like MEK/Toluene, Acetone/Methyl Isobutyl Ketone, etc.

The resulting emulsion/solvent is applied onto a structure, such as the aforementioned underlayer **1006**, or another substrate. Any suitable technique may be used to apply the emulsion/solvent. A preferred technique is specially

designed low pressure high volume spray coating, which provides fast, uniform application without streaks typical of brush coating or thickness variations and modulation of the interfaces that result from high shear blade or die extrusion coating methods for these very thin coatings.

The applied mixture is partially dried to remove at least some of the solvent, or substantially fully dried. The polymeric binder collapses onto the encapsulated microparticles as the solvent is removed during the drying. For example, in one aspect in which the binder is hydrophobic, the last solvent to leave the applied mixture is water, a non-solvent for the binder, which thus forces the hydrophobic binder to collapse onto the pigments. This also minimizes the residual stress in the dry coating. The drying is preferably performed using forced air under low temperature (less than about 75° C.) conditions.

The at least partially dried applied mixture is cured to restrict further expansion or contraction in the as-coated, stress-relieved layers during subsequent processing and exposure to environmental stresses to create a thin, high density recording layer **1008** having close-packed magnetic nanoparticles. In one approach, the at least partially dried applied mixture is irradiated. For example, UV light or other known radiation exposure is applied to cause crosslinking of the polymeric binder. In another approach, a different curing process is performed, such as by heating to increase reaction of thermally reactive functional groups in the encapsulated nanoparticle layer with the rubbery binder phase of the dried film.

As an option, lubricant may be added during formation of the recording layer **1008**, the lubricant molecules **1030** eventually becoming coupled to a surface of the recording layer **1008** upon formation of the recording layer **1008**. The lubricant molecules may be bound to the surface, embedded in the surface, or both. Again, preferably, an amount of the lubricant molecules along the surface of the recording layer **1008** is less than an amount to form a continuous lubricant film along the surface of the recording layer **1008**. In one illustrative approach, the lubricant molecules are positioned apart, on average, center to center, a distance in a range of about 2 to about 15 molecular radii along the surface of the recording layer **1008**.

In one approach, lubricant molecules **1030** are dispersed in the organic solvent phase and are carried to the surface during drying where they are grafted to the surface during the curing so that they form a stable low friction layer without movement of the lubricant molecules to the drive bearing and head surfaces. This in turn reduces head contamination.

In other approaches, a lubricant is applied to the outer surface of the completed recording layer **1008**.

In one illustrative example, a predominantly monodisperse suspension of magnetic nanoparticles such as  $\text{Co}_3\text{O}_4$ ,  $\text{CoFe}$ ,  $\text{Fe}_3\text{O}_4$ , or  $\text{Co}(\text{fcc})$  encapsulated with an aromatic polymer is combined with a rubbery polymer with radiation-curable end groups and side chains of sufficient chain length to provide a rubbery phase when bounded during cure to radiation curable end groups on the aromatic encapsulating layers of the dispersed nanoparticles. The resulting suspension is used to construct a close packed, thin recording layer **1008** in which a high density recording can be recorded. The rubbery chain attached to the aromatic encapsulating layer is terminated with an acrylic or methacrylic functional group capable of being UV cured to form a highly crosslinked matrix in which the magnetic particles are fully encapsulated by an aromatic glassy polymer held into a cohesive coating through swelling of the rubbery phase, e.g., acrylic termi-

nated low molecular weight polyester added to the solvent. UV curing of the solvent-swollen coating and polyester is carried out during drying.

Relative to current magnetic recording media, various benefits of a magnetic recording tape having the new underlayer and new recording layer thereon include, but are not limited to, one or more of: thinner recording layer, more uniform magnetic particle dispersion, smoother, less turbid interface between the underlayer and recording layer, higher glass transition temperature, lower occurrence or essential elimination of voids of magnetic particles in the recording layer, etc. Each of these benefits results in a magnetic recording tape that exhibits characteristics such as, but not limited to, one or more of: higher dimensional stability, greater tear resistance, higher recording resolution down to and below 1 nm, lower noise resulting in a higher signal to noise ratio, etc.

It will be clear that the various features of the foregoing systems and/or methodologies may be combined in any way, creating a plurality of combinations from the descriptions presented above.

It will be further appreciated that embodiments of the present invention may be provided in the form of a service deployed on behalf of a customer.

The inventive concepts disclosed herein have been presented by way of example to illustrate the myriad features thereof in a plurality of illustrative scenarios, embodiments, and/or implementations. It should be appreciated that the concepts generally disclosed are to be considered as modular, and may be implemented in any combination, permutation, or synthesis thereof. In addition, any modification, alteration, or equivalent of the presently disclosed features, functions, and concepts that would be appreciated by a person having ordinary skill in the art upon reading the instant descriptions should also be considered within the scope of this disclosure.

The descriptions of the various embodiments of the present invention have been presented for purposes of illustration, but are not intended to be exhaustive or limited to the embodiments disclosed. Many modifications and variations will be apparent to those of ordinary skill in the art without departing from the scope and spirit of the described embodiments. The terminology used herein was chosen to best explain the principles of the embodiments, the practical application or technical improvement over technologies found in the marketplace, or to enable others of ordinary skill in the art to understand the embodiments disclosed herein.

What is claimed is:

1. A tape cartridge, comprising:  
a housing; and  
a magnetic recording tape at least partially stored in the housing,  
the magnetic recording tape including a recording layer having encapsulated nanoparticles each comprising a magnetic nanoparticle encapsulated by an aromatic polymer-based encapsulating layer, and a polymeric binder binding the encapsulated nanoparticles.
2. The tape cartridge as recited in claim 1, comprising a nonvolatile memory coupled to the housing.
3. The tape cartridge as recited in claim 1, wherein an average diameter of the magnetic nanoparticles is in a range of 2 nanometers to 20 nanometers.
4. The tape cartridge as recited in claim 1, wherein the encapsulating layer is a layer selected from the group consisting of: a polyaromatic film, and a graphite-like dominated continuous film.

5. The tape cartridge as recited in claim 1, wherein the polymeric binder is an acrylic polymer.

6. The tape cartridge as recited in claim 1, wherein an average thickness of the recording layer is less than 0.2 microns.

7. The tape cartridge as recited in claim 1, wherein no wear particles are present in the magnetic recording tape.

8. A tape cartridge, comprising:

a housing; and

a magnetic recording tape at least partially stored in the housing,

the magnetic recording tape including an underlayer having encapsulated nanoparticles each comprising a magnetic nanoparticle encapsulated by an aromatic polymer, and a polymeric binder binding the encapsulated nanoparticles, wherein the underlayer is characterized as having an absolute value of a tensile storage modulus ( $E'$ ) thereof greater than 6 GPa.

9. The tape cartridge as recited in claim 8, comprising a nonvolatile memory coupled to the housing.

10. The tape cartridge as recited in claim 8, wherein the magnetic nanoparticles have an average magnetic field strength of less than 200 Oersted (Oe).

11. The tape cartridge as recited in claim 8, wherein an average concentration of the encapsulated nanoparticles in the underlayer is greater than 35 vol %.

12. The tape cartridge as recited in claim 8, wherein the underlayer is characterized as having an onset of at least 35° centigrade in a tensile storage modulus ( $E'$ ) vs. temperature plot.

13. The tape cartridge as recited in claim 8, wherein the underlayer is electrically conductive for assisting in dissipating a charge in the magnetic recording tape.

14. The tape cartridge as recited in claim 8, wherein no wear particles are present in the magnetic recording tape.

15. A tape cartridge, comprising:

a housing; and

a magnetic recording tape at least partially stored in the housing,

the magnetic recording tape including an underlayer and a recording layer above the underlayer,

the underlayer having first encapsulated nanoparticles each comprising a magnetic nanoparticle encapsulated by an aromatic polymer, and a polymeric binder binding the first encapsulated nanoparticles,

the recording layer having second encapsulated nanoparticles each comprising a magnetic nanoparticle encapsulated by an aromatic polymer-based encapsulating layer, and a polymeric binder binding the second encapsulated nanoparticles.

16. The tape cartridge as recited in claim 15, comprising a nonvolatile memory coupled to the housing.

17. The tape cartridge as recited in claim 15, wherein the magnetic nanoparticles of the underlayer have an average magnetic field strength of less than 200 Oersted (Oe).

18. The tape cartridge as recited in claim 15, wherein an average concentration of the first encapsulated nanoparticles in the underlayer is greater than 35 vol %.

19. The tape cartridge as recited in claim 18, wherein an average concentration of the first encapsulated nanoparticles in the underlayer is less than about 50 vol %.

20. The tape cartridge as recited in claim 15, wherein the underlayer is characterized as having an onset of at least 35° centigrade in a tensile storage modulus ( $E'$ ) vs. temperature plot.

21. The tape cartridge as recited in claim 15, wherein the underlayer is characterized as having an absolute value of a tensile storage modulus (E') thereof greater than 6 GPa.

22. The tape cartridge as recited in claim 15, wherein the underlayer is electrically conductive along an entire length 5 thereof for assisting in dissipating a charge in the magnetic recording tape.

23. The tape cartridge as recited in claim 15, wherein no wear particles are present in the magnetic recording tape.

24. The tape cartridge as recited in claim 15, wherein an 10 average diameter of the magnetic nanoparticles in the recording layer is in a range of 2 nanometers to 20 nanometers.

25. The tape cartridge as recited in claim 15, wherein the encapsulating layer is a layer selected from the group 15 consisting of: a polyaromatic film, and a graphite-like dominated continuous film; and wherein the polymeric binder in the recording layer is an acrylic polymer.
