(57) **ABSTRACT**
A baseline difference is determined between a slave line card time stamp corresponding to a slave line card frame sync signal and a master line card time stamp corresponding to a master line card frame sync signal. The slave line card generates subsequent slave line card time stamps for subsequent slave line card frame sync signals and the master line card generates subsequent master line card time stamps for subsequent master line card frame sync signals. Current differences are determined between subsequent slave line card time stamps and the subsequent master line card time stamps and the current differences are compared to the baseline difference. When a mismatch difference occurs (current difference differs from the baseline difference), the mismatch difference causes a phase-locked loop in the master line card to be adjusted or an offset to be provided to the master line card time of day counter.

FSYNC MISMATCH TRACKING

BACKGROUND

Field of the Invention

This disclosure relates to network timing and more particularly to reducing errors in network timing signals.

Description of the Related Art

Network communication boxes use timing protocols to ensure time of day (ToD) counters in the network are synchronized. Frame sync (FSYNC) signals are used to update time of day counters at the same time in the network. Any delay/offset and process, voltage, temperature (PVT) variation between the FSYNC signals being supplied to the ToD counters in each line card in the network box results in an error that is classified as Continuous Time Error (CTE). By way of example, the CTE budget for a network box is 5 ns for Class D type network boxes. Reducing sources of timing error in network boxes would give greater flexibility to designers to meet the CTE budget.

SUMMARY OF EMBODIMENTS OF THE INVENTION

Accordingly, in one embodiment an apparatus includes a master line card that includes a master line card time of day counter, a phase-locked loop supplying a master timing card clock signal from which a plurality of master line card frame sync signals are generated. Each of the master line card frame sync signals indicates when a roll over event for the master line card time of day counter occurs. The master line card further includes a master line card time stamp circuit to provide a plurality of master line card time stamps corresponding to the plurality of master line card frame sync signals. The apparatus further includes a slave line card that includes a slave line card time of day counter and a slave line card time stamp circuit that generates a plurality of slave line card time stamps corresponding to a plurality of slave line card frame sync signals generated on the slave line card. Each of the slave line card frame sync signals indicates when a roll over event for the slave line card time of day counter occurs. Compare logic compares one of the plurality of slave line card time stamps and one of the plurality of master line card time stamps and generates a baseline difference. The compare logic is configured to generate a second difference based on comparison between a second of the plurality of slave line card time stamps and a second one of the plurality of master line card time stamps. Control logic is responsive to the baseline difference not being equal to the second difference, to generate a mismatch difference indicative of a difference between the baseline difference and the second difference and to compensate for the mismatch difference.

In another embodiment a method includes generating a plurality of slave line card time stamps for a respective plurality of slave line card frame sync signals generated on a slave line card. A master line card generates a plurality of master line card time stamps for a respective plurality of master line card frame sync signals. One of the plurality of slave line card time stamps is compared to one of the plurality of master line card time stamps to generate a baseline difference. A second difference is generated based on a comparison of a second of the plurality of slave line card time stamps to a second of the plurality of master line card time stamps. The second difference not being equal to

2

the baseline difference is compensated for by adjusting at least one timing aspect of the master line card. In an embodiment, the phase-locked loop in the master line card is adjusted based on a difference between the second difference and the baseline difference, the one timing aspect being associated with the phase-locked loop. In another embodiment, the second difference not being equal to the baseline difference is compensated for by providing an offset to a time of day counter on the master line card, the offset corresponding to the difference between the second difference and the baseline difference, the one timing aspect being the offset.

In another embodiment a method includes generating a baseline difference between occurrence of a first slave line card frame sync signal on a slave line card and a first master line card frame sync signal on a master line card. A second difference is generated between occurrence of a second slave line card frame sync signal and a second master line card frame sync signal. The method further includes adjusting at least one aspect of the master line card to compensate for the second difference not being equal to the baseline difference.

BRIEF DESCRIPTION OF THE DRAWINGS

The present invention may be better understood, and its numerous objects, features, and advantages made apparent to those skilled in the art by referencing the accompanying drawings.

FIG. 1 illustrates a typical architecture of network communication box with a slave line card, a master timing card, and multiple master line cards.

FIG. 2 illustrates the closed loop utilized to keep the slave line card aligned with the timing of the incoming data stream.

FIG. 3 illustrates that the F SYNC and CLK signal are distributed open loop to the master timing cards.

FIG. 4 illustrates a line card (master or slave) according to an embodiment that compensates for temperature variation to reduce CTE.

FIG. 5 illustrates the time stamp compare operation that establishes the baseline difference between a slave line card F SYNC time stamp and a master line card F SYNC time stamp.

FIG. 6 illustrates the tracking operation to compare current time stamp differences to the baseline time stamp difference.

FIG. 7 illustrates a high level block diagram of an embodiment of a phase-locked loop used on the line cards (master and slave).

FIG. 8 illustrates a flow diagram for tracking the time stamp differences to reduce CTE in network communication boxes.

The use of the same reference symbols in different drawings indicates similar or identical items.

DETAILED DESCRIPTION

FIG. 1 illustrates a typical architecture of network communication box **100** with a slave line card (LC) **101**, a master timing card (TC) **103**, and multiple master line cards **105**. Embodiments can have, e.g., 64 master line cards. The data_out **109** from each line card is time stamped using time stamps from local time of day (ToD) counters **111**. The slave line card **101** receives timing information from a selected one of a plurality of incoming data streams on data_in **116** that provides the network time of day to which the communication system **100** maintains alignment.

The master timing card **103** supplies a global F SYNC signal and system clock signal (CLK) to the slave line card **101** generated using PLL **117** and dividers (not shown). The FSYNC signal is also referred to as the SYNC signal in certain contexts as the signal can have different names (SYNC or F SYNC) at the integrated circuit level inside the network box or system level. The signal will be referred to as the F SYNC signal herein for ease of reference. The global FSYNC signal can be embedded inside a serial stream, e.g., in the CLK signal, which conveys the position of the global F SYNC edge through a pulse width modulation of the CLK signal or other data transfer methods. The master timing card **103** supplies the CLK and global F SYNC signal to all of the master line cards **105** over backplane **119**. The global F SYNC signal is a global signal inside the network system box **100** that signifies the right moment/edge for the Time of Day (ToD) counters **111** to rollover. The time of day counters maintain the date and time. The global F SYNC signal has a frequency range of, e.g., 16 kHz to pp2s (pulse per 2 seconds). In many network systems the FSYNC signal is 1 pulse per second (1 PPS). F SYNC is generally an integer divided down and edge aligned version of the system clock signal CLK. The global F SYNC output from the master timing card **103** is used by all the line cards for their ToD rollover alignment. The various ToD counters **111** contain the same value and turnover at the same time based on the global F SYNC signal. Each of the line cards **101** and **105** generate a local F SYNC signal by dividing the CLK generated by PLL **121** in a divider (not shown in FIG. 1) to the desired frequency, e.g., 1 PPS that should be aligned to the global F SYNC signal.

One challenge in a network communication box is to keep the ToD on the slave line card aligned with the network timestamps from the incoming data stream. That is accomplished by deriving the exact position of the F SYNC edge using a precision time protocol (PTP) servo loop that uses the time information inside the incoming packet stream on data_in **116** to the slave line card **101**. Another challenge is to keep the ToD counters across different line cards in perfect alignment over process, voltage, and temperature (PVT) so that the time stamps indicating the ToD sent with the data_out **109** from the master line cards are always aligned with each other and the incoming network time. That is, the time stamps sent with the master line card data out should reflect the current network time of day.

As mentioned above, the slave line card ToD should be identical to the time provided by the incoming data stream. FIG. 2 illustrates that the slave line card **101** uses a closed loop **201** to keep the slave line card aligned with the timing of the incoming data stream. The selected input data stream, the slave line card **101**, and the master timing card **103** operate in a Precision Time Protocol (PTP)/1588 closed loop to maintain alignment between the ToD and the Grandmaster time. The master timing card provides the clock signal (CLK) and the global frame sync (FSYNC) signal that are adjusted to maintain the alignment. The Grandmaster (the selected input data stream) provides time stamps that the MCU **108** on the slave line card **101** compares to the ToD on the slave line card and provides any necessary phase and frequency adjustments to the PLL **117** on the master timing card to adjust CLK and F SYNC signal (as indicated by Δt) to compensate for any differences in the slave line card timing and Grandmaster timing. The PLL **121** in the slave line card is locked to the PLL in **117** using global F SYNC and the CLK signal as the reference clock and global F SYNC provided to the backplane indicates when the edge of

the local F SYNC signal should occur. The PLL **117** is in turn locked using the PTP loop to the network timing of the GrandMaster. The FSYNC signal is used to indicate when a rollover, e.g., of a particular bit of the ToD counter should occur after, e.g., each 1 second interval.

There are fixed delays associated with the backplane and the circuits of the slave line card **101** and the master timing card **103** and the signal lines between them. Those fixed delays can be calibrated out in test. In addition, the PTP/1588 closed loop system adjusts the CLK and FSYNC pair generated by the master timing card **103** such that the slave line card ToD remains aligned with the network time of the chosen incoming data_in stream using adjustments based the PTP/1588 loop algorithm.

The master timing card CLK/FSYNC pair is globally distributed over the backplane **119** to all of the master line cards **105**. While the slave line card is closed loop and continuously corrected by adjusting the master timing card PLL **117**, the CLK/FSYNC pair distribution is open loop to the master line cards **105** as illustrated by **301** in FIG. 3. Thus, the master line cards have delay mismatch with the slave line card due to temperature variation, especially real time temperature variation that has not been calibrated out at manufacturing or test. The master line cards have process, voltage, and temperature coefficient differences. In addition, the temperature of the line cards can vary inside the communications box **100** depending on location. While fixed mismatches can be calibrated out at test after careful design and manufacturing (process and voltage variations), temperature variation mismatch accounts for the bulk of the network time error between the line cards that cannot be easily calibrated out. Since line cards, and their components have different temperature coefficients and line card temperature varies over time and within the box, such temperature change over time causes CTE.

FIG. 4 illustrates a line card (master or slave) according to an embodiment that compensates for temperature variation and reduces CTE. Note that the master line cards utilize mismatch tracking to compensate for temperature variation while the slave line card utilizes the PTP loop to remain locked to the network timing. Each line card includes an integrated circuit **400** that includes a phase-locked loop **401** that generates a clock signal **402** for the local ToD counter **403** (corresponding to ToD **111** in FIG. 1). In addition, divider **404** divides down the generated clock signal to generate the local FSYNC signal **408** that is the rollover signal for ToD **403**. In addition, the FSYNC signal **408** is fed back to time stamper **405**. In an embodiment the divider **404** counts N locally generated CLK cycles and then issues a pulse (FSYNC) indicating the N count has been reached. The counter then resets and counts again, thus issuing a pulse every N cycles of CLK **402**. The master timing card (see FIG. 1) distributes the global CLK signal **410** and the global F SYNC signal **412** over the backplane to each line card. The PLL **401** on the integrated circuit **400** utilizes the CLK signal **410** as the PLL reference clock signal. The global FSYNC signal **412** is used conceptually to control the divider **404** to align the locally generated FSYNC signal with the global F SYNC signal **412** distributed over the backplane. In an embodiment, the global F SYNC signal **412** is time stamped in time stamper **422**, which provides the time stamp to compare and control logic **414**. That compare may be used to adjust the PLL **401** to align the local F SYNC signal **408** and the global FSYNC signal **412**. The goal is to ensure a zero delay between the global F SYNC and the local F SYNC. That goal can be modified as described herein to improve system FSYNC accuracy across line cards. The

5

global FSYNC signal **412** can also be used to ensure divider **404** restarts its count of the PLL at the right time and with the right value.

In order to compensate for temperature change, different temperature coefficients, and different temperatures within the network communications box, the line cards in the illustrated embodiment time stamp the local F SYNC signal **408** in time stamper **405**. Thus, each master line card determines a master line card F SYNC time stamp and the slave line card determines a slave line card FSYNC time stamp. Each master line card (or the slave line card) determines a baseline time stamp difference (baseline mismatch) between the slave line card FSYNC time stamp and the master line card FSYNC time stamp in time stamp compare and control logic **414**. The baseline difference between each of the master line cards and the slave line card is likely to be different. The time stamp compare logic resides on either the slave line card or on each master line card. If the compare logic resides on the slave line card, the master line cards send their time stamp information to the slave line card for the compare operation. If the compare logic resides on the master line card, the slave line card sends its time stamp information to the master line cards for the compare operation to establish the baseline difference. Periodically, e.g., every 1 second (or longer or shorter according to the needs of the particular system), the slave line card and each of the master line cards time stamp a currently generated F SYNC and determine a current difference between the slave line card generated FSYNC and the master line card generated FSYNC. The slave line card is locked to the network timing of the incoming data stream (the Grandmaster) but the master line cards are running open loop. The current time stamp difference is compared to the baseline time stamp difference and if the compare result indicates the difference has remained constant, no action need be taken. However, if the compare result is non-zero thereby indicating a mismatch difference, the timing of master line card is out of sync with the timing of the slave line card. In an embodiment, the master line card compensates for the mismatch difference by adjusting PLL **401** based on the non-zero compare result (the mismatch difference) to cause the compare result (mismatch difference) to return to zero. In that way, as temperature changes, the master line cards adjust their PLL timing to reduce CTE. Note that if there is a mismatch difference, mismatch compensation accounts for the unequal delays caused by, e.g., temperature variation between line cards of the I/O buffers and backplane buffers. The mismatch compensation can result in the delay between global FSYNC **412** and local FSYNC **408** being non-zero. The mismatch compensation helps ensure that local FSYNCs occur at the same time across line cards given different temperatures and delays associated with different line cards.

Alternatively, to compensate for the mismatch difference, the master line card supplies an offset **418** to the time of day counter **403** with the offset corresponding to the non-zero compare results (mismatch difference). The offset can be positive or negative. Thus, ToD counter **403** counts the next interval between FSYNC pulses to be shorter or longer based on the offset. That may be a particularly useful approach if the ToD counter is located on the same integrated circuit with the PLL and the compare logic measuring the time stamp differences but in other embodiments the ToD counter is located on another integrated circuit in the line card. Thus, the non-zero compare results can be compensated for in several ways, e.g., by adjusting the master line card PLL or supplying an offset to the ToD counter.

6

FIG. **5** illustrates the time stamp compare operation that establishes the baseline difference between a slave line card F SYNC time stamp and a master line card F SYNC time stamp. Assume FIG. **4** illustrates a master line card and the compare logic resides in each of the master line cards. In an embodiment, the compare and control logic **414** is implemented as digital logic in integrated circuit **400** or programmable logic (e.g., a microcontroller unit (MCU)) or in any appropriate combination of programmable and digital logic in integrated circuit **400** or elsewhere on the master line card. Time stamper **405** receives the feedback of FYSNC signal **408** generated on the master line card and supplies the time stamp to a time stamp register **501** on the master line card. The slave line card has identical hardware shown as time stamper **505** receiving the feedback of the locally generated F SYNC signal and stores the time stamp in the slave time stamp register **507**. The two time stamps are compared in the subtraction circuit **509** and the baseline difference in the timestamps is stored in the baseline time stamp register **511**. If the compare logic is in the master line cards, the slave line card sends the time stamp information to each of the master line cards. A serial bus **420** (see FIG. **4**) carries the time stamp information and other control information. In an embodiment, the slave line card broadcasts the time stamp information to all of the master line cards. If the compare logic is in the slave line card, the slave line card receives the master line card time stamps, performs the compare for each master line card, and stores the baseline differences for all the master line cards.

Once the baseline difference between the master line card and the slave line card time stamps is established, the current difference (mismatch) is tracked in order to compensate for temperature. FIG. **6** illustrates the tracking operation. Time stamper **405** time stamps a current local F SYNC **408** and stores the time stamp result in the master line card time stamp register **501**. The slave line card time stamps the local slave line card FSYNC in time stamper **505** and stores the time stamp in slave line card time stamp register **507**. Compare logic (subtraction circuit) **509** compares the two time stamps and generates a current time stamp difference **515**. Compare logic **516** compares the current difference and the baseline difference and supplies the difference. That difference determines an adjustment **416** to PLL **401** (see FIG. **4**) to zero out the difference from the baseline difference or the difference determines the offset **418**. If the slave line card does the compares, the slave line card sends the respective difference to the appropriate master line card.

FIG. **7** illustrates a high level block diagram of a phase-locked loop **700** utilized in an embodiment of PLL **401**. The illustrated PLL is a digital PLL that time stamps the reference clock from CLK **410** and the feedback clock (FBCLK) **701** and supplies the time stamps to a digital phase and frequency detector (PFD) **702**. Since the PLL **700** receives the distributed clock signal as a reference clock, the PLL is frequency locked to the CLK signal. Thus, all the master line cards (along with the slave line card) are frequency locked to the CLK signal and the time stampers are all frequency locked since the PLL are frequency locked. Once PLL **700** is locked to CLK **410**, divider **404** generates the F SYNC signal **408** that is looped back to time stamper **405**. In an embodiment, the PLL **700** has a loop bandwidth of between, e.g., 40 Hz and 100 Hz. The digital PFD **702** supplies the phase difference to digital loop filter **703**, that in turn controls the oscillator **704**. In an embodiment, the oscillator **704** is a voltage controlled oscillator (VCO) that supplies a 1 GHz clock signal while the backplane distributed reference clock signal (CLK) **410** from the master timing card is,

e.g., 10 MHz. Those frequencies are simply examples and in other embodiments, the frequencies of the distributed CLK signal and the VCO generated clock signal **402** are different. In an embodiment the time stamper **405** on the master line card (and **505** for the slave line card) is clocked by the output of the VCO **704**. In an embodiment the time stamper **405** (and **505**) is implemented as a high precision time to digital converter such as one described in the patent entitled "USE OF A RECIRCULATING DELAY LINE WITH A TIME-TO-DIGITAL CONVERTER", U.S. Pat. No. 10,067,478, which patent is incorporated herein by reference.

There are several ways that the PLL **700** can be adjusted based on the difference between the current time stamp mismatch and the baseline time stamp mismatch. Referring still to FIG. 7, the PLL can be adjusted by adjusting the feedback divider **705**. In other embodiments in which the PFD **702** receives digital values, the adjustment can be made by adjusting the digital time stamp **707** of the feedback clock being supplied to the PFD **702** or the digital time stamp **709** of the reference clock signal with an offset corresponding to the difference. In still other embodiments, by way of example, a non-integer output divider (not shown in FIG. 7) is adjusted, output divider **404** is adjusted, or an I/O delay offset is changed. The correction is preferably applied slowly to zero out the difference between the current mismatch and the baseline mismatch so as not to cause an undesirable large perturbation to the VCO output signal or other signals based on the VCO output signal.

FIG. 8 illustrates a flow chart for tracking the time stamp differences to reduce CTE in network communication boxes. In **801**, responsive to a power on condition and after the local PLL has locked to the CLK signal and the timing of the incoming data stream, or responsive to another selected time point, the slave line card determines a time stamp for the locally generated F SYNC signal. At **803**, responsive to a power on condition and after the local PLL has locked to the CLK signal, or responsive to another selected time point, each of the master line cards determines a time stamp for the locally generated F SYNC. Then, either the master line cards send the time stamps to the slave line card or the slave line card sends the time stamp to the master line cards, e.g., in a broadcast operation. In **805** each of the master line cards (or the slave line card) determines a baseline difference between the F SYNC time stamp of the slave line card and the F SYNC time stamp of the master timing card and stores the baseline difference (baseline mismatch) for use in tracking. Alternatively, the slave line card determines and stores the baseline difference for each of the master line cards. In **806**, the line cards wait a predetermined amount of time before the next time stamps are compared. Once the predetermined time period has passed, in **807**, each of the master line cards periodically determines, e.g., once every 1 second, a current master line card F SYNC time stamp and the slave line card periodically determines a current slave line card FSYNC time stamp. Either each of the master line cards send the slave line card the current master line card F SYNC time stamp or the slave line card sends the master line cards the current slave line card F SYNC time stamp. In **809** the current difference between master and slave time stamps is determined and compared in **811** to the baseline difference.

If the slave line card performs all the compares for the master line cards to determine whether the current time stamp differs from the baseline time stamp, the slave line card sends the master line cards the results of the compare or at least the results of the compare that require the PLL on the master line card to be adjusted or require an offset to the ToD counter. Less traffic will result on the bus if the

compares are distributed and performed on the master line cards since that is where the compare results will be utilized. In **815** each of the master line cards (or the slave line card) checks if the current difference and baseline difference are the same. Note that the change from the baseline difference can be positive or negative. If the compare result is non-zero indicating a mismatch difference (i.e., the current difference between master time stamp and slave time stamp is not equal to the baseline difference), the path delays between the slave line card and the master line card have changed likely due to temperature and in **817** the master line card adjusts its PLL based on the non-zero difference to eliminate the non-zero difference by, e.g., adjusting a phase of the master line card PLL according to the non-zero difference or adjusting other PLL parameters (e.g., divider values, etc.) described earlier. For example, assume the slave line card time stamp was initially **100** and the master line card initial time stamp was **200** and thus the baseline difference was **100**. Assume for one of the periodic checks, the master line card time stamp was **1201** and the slave line card was **1100** and thus the current difference is **101**. That implies the master line card has less delay since the count moved forward and the PLL should be adjusted to account for the delay change and match the baseline difference of **100**. Less delay can be the result of, e.g., the master line card being in a cooler location in the network communications box, a different temperature coefficient, or both. Alternatively, rather than adjusting the PLL in **817**, the master line card supplies an offset to the ToD counter with the offset corresponding to the mismatch difference (non-zero difference between the baseline difference and the current difference). The flow then returns to **806** to periodically wait for the next periodic time stamp compare. If the difference between the current difference and the baseline difference is zero in **815** (differences are equal) no action needs to be taken to adjust the master line card PLL and the flow returns to **806** to wait for the next periodic check.

In an embodiment the system includes a temperature sensor **424** (see FIG. 4) in each line card in the system, and the temperature readings are stored in a table in or accessible to compare and control logic **414**. Assume each line card is calibrated at, e.g., 25° C. As the temperature changes and the mismatch is tracked resulting in adjustments to the master line card to compensate for the mismatches, a temperature coefficient is calculated for each master line card that specifies, e.g., how much compensation should be used per degree change in temperature, and that temperature coefficient can be used independently by each master line card along with mismatch tracking. Each master line card looks up the compensation value based on its current temperature and applies it to compensate for a temperature change. Use of the temperature coefficient by the master line cards can reduce the frequency of the mismatch tracking and reduce the size of the mismatch. In addition, the use of the temperature sensor and compensation using the temperature coefficient helps to keep the mismatch low in case of inter card communication failure or limitations in bandwidth.

While time stamping is one way to track the mismatch, other mechanisms can be used for mismatch tracking. For example, another approach uses analog or digital phase and frequency detectors (PFDs). The analog or digital PFDs utilize additional physical signaling so the rising edge of the FSYNCs can be compared in the PFD. In addition, PFD output should account for mismatch created by the additional physical signaling. In another alternative, messaging and calibration algorithms can be used in the packets sent between the slave line card and the various master line cards.

The calibration using messaging involves sending a single or multiple calibration packets with time stamps (indicating when the packets are sent) through all the line card ports and calculation of the mismatch using the timestamps. The calculated mismatch is then corrected through the master line card PLL or an offset is provided to on the master line card ToD counter.

Thus, a way to reduce CTE for the communication box has been described by comparing a current time stamp difference to a baseline time stamp difference for each of the master line cards and adjusting a master line card PLL according to the compare. The description of the invention set forth herein is illustrative and is not intended to limit the scope of the invention as set forth in the following claims. Variations and modifications of the embodiments disclosed herein may be made based on the description set forth herein, without departing from the scope of the invention as set forth in the following claims.

What is claimed is:

1. An apparatus comprising:
 - a master line card including a master line card time of day counter, a phase-locked loop supplying a master timing card clock signal from which a plurality of master line card frame sync signals are generated, each of the master line card frame sync signals indicating when a roll over event for the master line card time of day counter occurs, and a master line card time stamp circuit to provide a plurality of master line card time stamps corresponding to the plurality of master line card frame sync signals;
 - a slave line card including a slave line card time of day counter and a slave line card time stamp circuit to generate a plurality of slave line card time stamps corresponding to a plurality of slave line card frame sync signals generated on the slave line card, each of the slave line card frame sync signals indicating when a roll over event for the slave line card time of day counter occurs;
 - compare logic to compare one of the plurality of slave line card time stamps and one of the plurality of master line card time stamps and generate a baseline difference, the compare logic being configured to generate a second difference according to a comparison between a second one of the plurality of slave line card time stamps and a second one of the plurality of master line card time stamps; and
 - control logic responsive to the baseline difference not being equal to the second difference, to generate a mismatch difference indicative of a difference between the baseline difference and the second difference and to compensate for the mismatch difference.
2. The apparatus as recited in claim 1 wherein the master line card is configured to adjust the phase-locked loop based on the mismatch difference between the second difference and the baseline difference to thereby compensate for the mismatch difference and undo the mismatch difference.
3. The apparatus as recited in claim 2 wherein the phase-locked loop is adjusted in multiple steps to undo the difference.
4. The apparatus as recited in claim 1 wherein the master line card is configured to supply an offset corresponding to the mismatch difference to the master line card time of day counter to compensate for the mismatch difference.
5. The apparatus as recited in claim 1 wherein the control logic is responsive to the baseline difference being equal to the second difference, to not adjust the phase-locked loop in the master line card.

6. The apparatus as recited in claim 1 wherein the master line card further comprises the compare logic.

7. The apparatus as recited in claim 1 wherein the slave line card further comprises the compare logic.

8. The apparatus as recited in claim 1 wherein the master line card further comprises:

a first storage location to store at least one of the slave line card time stamps; and

a second storage location to store the baseline difference.

9. The apparatus as recited in claim 8 wherein the first and second storage locations are on an integrated circuit on which the phase-locked loop is disposed.

10. The apparatus as recited in claim 1 further comprising a second master line card.

11. A method comprising:

generating a plurality of slave line card time stamps for a respective plurality of slave line card frame sync signals generated on a slave line card;

generating a plurality of master line card time stamps for a respective plurality of master line card frame sync signals generated on a master line card;

comparing one of the plurality of slave line card time stamps to one of the plurality of master line card time stamps and generating a baseline difference;

generating a second difference based on a comparison of a second of the plurality of slave line card time stamps to a second of the plurality of master line card time stamps; and

compensating for the second difference not being equal to the baseline difference by adjusting at least one timing aspect of the master line card.

12. The method as recited in claim 11 wherein the compensating comprises adjusting a phase-locked loop in the master line card based on a difference between the second difference and the baseline difference to eliminate the difference between the second difference and the baseline difference, the one timing aspect being associated with the phase-locked loop.

13. The method as recited in claim 11 wherein the compensating comprises providing an offset to a time of day counter on the master line card, the offset corresponding to a difference between the second difference and the baseline difference, the one timing aspect being the offset.

14. The method as recited in claim 11 further comprising: determining a temperature coefficient for the master line card based on a plurality of temperature readings and a plurality of mismatch compensations; and compensating for temperature change based on the temperature coefficient and a current temperature reading.

15. The method as recited in claim 11 further comprising: providing the plurality of slave line card time stamps to the master line card from the slave line card; and comparing the baseline difference and the second difference in the master line card.

16. The method as recited in claim 11 further comprising comparing the baseline difference and the second difference in the slave line card.

17. The method as recited in claim 16 further comprising the master line card providing the plurality of master line card time stamps to the slave line card.

18. The method as recited in claim 11 further comprising: storing one or more of the plurality of slave line card time stamps in one or more storage locations in the master line card; and storing the baseline difference in the master line card.

19. The method as recited in claim 11 further comprising:

11

generating a second plurality of second master line card time stamps for a respective second plurality of second master line card frame sync signals generated on a second master line card;

comparing one of the plurality of slave line card time stamps and one of the second plurality of second master line card time stamps and generating a second baseline difference;

generating a third difference based on a comparison using another one of the plurality of slave line card time stamps and another one of the second plurality of second master line card time stamps; and

compensating for the third difference not being equal to the second baseline difference by adjusting a second phase-locked loop in the second master line card, the adjusting based on a difference between the third difference and the second baseline difference or compensating for the third difference not being equal to the second baseline difference by providing a second offset to a second time of day counter on the second master line card, the second offset corresponding to the difference between the third difference and the second baseline difference.

20. A method comprising:

generating a baseline difference between occurrence of a first slave line card frame sync signal on a slave line card and a first master line card frame sync signal on a master line card;

generating a second difference between occurrence of a second slave line card frame sync signal and a second master line card frame sync signal; and

adjusting at least one aspect of the master line card to compensate for the second difference not being equal to the baseline difference.

21. The method as recited in claim **20** further comprising:

generating a plurality of additional differences between additional slave line card frame sync signals and additional master line card frame sync signals;

comparing the additional differences to the baseline difference to generate additional values; and

12

compensating for respective ones of the additional values being non-zero and not compensating for respective ones of the additional values being zero.

22. The apparatus as recited in claim **1** wherein the master line card further comprises the control logic.

23. The apparatus as recited in claim **1** further comprising a serial bus coupling the master line card and the slave line card and the slave line card is configured to supply the slave line card time stamps to the master line card over the serial bus.

24. The apparatus as recited in claim **10** wherein the second master line card comprises:

a second master line card time of day counter;

a second phase-locked loop supplying a second master timing card clock signal from which a plurality of second master line card frame sync signals are generated, each of the second master line card frame sync signals indicating when a roll over event for the second master line card time of day counter occurs;

a second master line card time stamp circuit to provide a plurality of second master line card time stamps corresponding to the plurality of second master line card frame sync signals;

second compare logic to compare one of the plurality of slave line card time stamps and one of the plurality of second master line card time stamps and generate a second baseline difference the second compare logic being configured to generate a third difference based on a comparison between another of the plurality of slave line card time stamps and another of the plurality of second master line card time stamps; and

second control logic responsive to, at least in part, the second baseline difference not being equal to the third difference, to generate a second mismatch difference indicative of a difference between the second baseline difference and the third difference and to compensate for the second mismatch difference by adjusting the second phase-locked loop according to the second mismatch difference or supplying a second offset to the second master line card time stamp circuit that corresponds to the second mismatch difference.
