(57) **ABSTRACT**

Systems, devices, and methods for identifying an individual in both cooperative and non-cooperative situations are provided. In one aspect, for example, a system for identifying an individual can include an active light source capable of emitting electromagnetic radiation having at least one wavelength of from about 700 nm to about 1200 nm, and an imager device positioned to receive the electromagnetic radiation upon reflection from an individual to generate an electronic representation of the individual. The system can also include an image processing module functionally coupled to the imager device to receive the electronic representation. The image processing module processes the electronic representation into an individual representation having at least one substantially unique identification trait. The imager device can include a semiconductor device layer having a thickness of less than about 10 microns, at least two doped regions forming a junction, and a textured region positioned to interact with the electromagnetic radiation, and can have an external quantum efficiency of at least about 33% for at least one wavelength of greater than 800 nm.

BIOMETRIC IMAGING DEVICES AND ASSOCIATED METHODS

PRIORITY DATA

[0001] The present application claims the benefit as a continuation of U.S. patent application Ser. No. 14/864,592, filed on Sep. 24, 2015 and entitled “Biometric Imaging Devices and Associated Methods,” which claims the benefit as a continuation of U.S. patent Ser. No. 13/549,107, filed on Jul. 13, 2012 and entitled “Biometric Imaging Devices and Associated Methods,” which claims the benefit of U.S. Provisional Application No. 61/507,488, filed on Jul. 13, 2011 and entitled “Biometric Imaging Devices and Associated Methods,” each of which is incorporated herein by reference in their entireties.

BACKGROUND

[0002] Biometrics is the study of signatures of a biological origin that can uniquely identify individuals. Biometric technology has increased in interest in recent years, and can be classified in two groups, cooperative identification and non-cooperative identification. Cooperative biometric identification methods obtain biometric readings with the individual’s knowledge, and typically detect biological signatures such as finger prints, palm prints, and iris scans. Non-cooperative biometric identification methods obtain biometric readings without the person’s knowledge, and typically detect facial, speech, and thermal signatures of an individual. This disclosure focuses on devices and methods that can detect various biometric signatures of both cooperative and non-cooperative individuals, through the use of imaging devices.

[0003] Facial and iris detection are some of the more common signatures used by security applications for identifying individuals. These methods of detection involve two independent steps, an enrollment phase where biometric data is collected and stored in a database and a query step, where unknown biometric data is compared to the database to identify the individual. In both of these steps, a camera can be used to collect and capture the images of the individual’s face or iris. The images are processed using algorithms that deconstruct the image into a collection of mathematical vectors which, in aggregate, constitute a unique signature of that individual.

[0004] Digital imaging devices are often utilized to collect such image data. For example, charge-coupled devices (CCDs) are widely used in digital imaging, and have been later improved upon by complementary metal-oxide-semiconductor (CMOS) imagers having improved performance. Many traditional CMOS imagers utilize front side illumination (FSI). In such cases, electromagnetic radiation is incident upon the semiconductor surface containing the CMOS devices and circuits. Backside illumination CMOS imagers have also been used, and in many designs electromagnetic radiation is incident on the semiconductor surface opposite the CMOS devices and circuits.

[0005] As a major caveat to biometric signature acquisition, however, pigmentation of the skin and/or iris can affect the ability to collect robust data, both in the enrollment phase as well as in the future query phase. The pigmentation can mask or hide the unique structural elements that define the values of the signature mathematical vectors.

SUMMARY

[0006] The present disclosure provides systems, devices, and methods for identifying an individual in both cooperative and non-cooperative situations. In one aspect, for example, a system for identifying an individual can include a light source capable of emitting electromagnetic radiation having at least one wavelength of from about 700 nm to about 1200 nm, and an imager device positioned to receive the electromagnetic radiation upon reflection from an individual to generate an electronic representation of the individual. The system can also include an image processing module functionally coupled to the imager device to receive the electronic representation. The image processing module processes the electronic representation into an individual representation having at least one substantially unique identification trait. The imager device can include a semiconductor device layer having a thickness of less than about 10 microns, at least two doped regions forming a junction, and a textured region positioned to interact with the electromagnetic radiation. The imaging device has an external quantum efficiency of at least about 33% for electromagnetic radiation having at least one wavelength of greater than 800 nm.

[0007] Various light sources are contemplated, and any light source capable of delivering electromagnetic radiation within the ranges utilized by the present devices and systems is considered to be within the present scope. In one aspect, for example, the light source can be an active light source. In yet another aspect, the light source may be a passive light source or in other words ambient light from the surroundings. In another aspect, the active light source can be two or more active light sources each emitting infrared electromagnetic radiation at distinct peak emission wavelengths. In one specific aspect, the two or more active light sources can emit infrared electromagnetic radiation at about 850 nm and about 940 nm. In another aspect the two or more active light sources can emit infrared electromagnetic radiation at about 850 nm and about 1060 nm.

[0008] The semiconductor device layer used in the imager device can include any useful semiconductor material. In one aspect, however, the semiconductor device layer can be comprised of silicon. In one specific aspect, a silicon-based imager device having device layer with a thickness less than about 10 microns can have a response time of from about 0.1 ms to about 1 ms and an external quantum efficiency of at least about 33% for electromagnetic radiation having at least one wavelength of greater than 800 nm. In another aspect, the response time can be from about 0.1 ms to about 16 ms. In yet another specific aspect, a silicon-based imager device having a semiconductor device layer with a thickness less than about 10 microns can have a response time of from about 0.1 ms to about 1 ms and an external quantum efficiency of at least about 11% for electromagnetic radiation having at least one wavelength of greater than 940 nm.

[0009] In another aspect, the imager device is capable of capturing the electronic representation with sufficient detail to identify the at least one substantially unique identification trait using electromagnetic radiation emitted from the active light source having at least one wavelength of from about 700 nm to about 1200 nm and having a scene radiance impinging on the individual at 3 meters that is at least 0.1 mW/mm². In yet another aspect, the imager device is capable of capturing the electronic representation with sufficient detail to identify the at least one substantially unique identification trait using electromagnetic radiation emitted

from the active light source having at least one wavelength of from about 800 nm to about 1000 nm and having a scene radiance impinging on the individual at 3 meters that is from about 1.0 mW/mm² to about 100 mW/mm². In a further aspect, the imager device can operate on an electronic global shutter to capture the electronic representation.

[0010] In yet another aspect, the system can include an analysis module functionally coupled to the image processing module, wherein the analysis module is operable to compare the at least one substantially unique identification trait with a known identification trait to facilitate identification of the individual.

[0011] In a further aspect, the system can include an automatic pan and zoom module operable to move at least one of the light source or the imager device in order to track the individual.

[0012] In some aspects, the imager device can include at least two imager devices. In one specific aspect, the at least two imager devices includes a first imager device positioned and operable to generate a facial electronic representation of the individual and a second imager device positioned and operable to generate an iris electronic representation of the individual. In another specific aspect, the system can include an automatic pan and zoom module operable to move at least one of the light source or the imager device and a process module to analyze the facial electronic representation and provide the pan and zoom module coordinates for the face and iris.

[0013] In some aspects, the system can be configured to be concealed from the individual being identified. In one aspect, for example, the system can be concealed from the individual behind an infrared transparent medium that is visually opaque. The infrared transparent medium can be a plane of glass or plastic being at least partially coated with an infrared transparent paint or other infrared transparent medium. In one aspect metal particles can be impregnated into at least a portion of the infrared transparent medium. In yet another aspect, quantum dots may be disposed on the infrared transparent medium such that infrared light is transmitted through the medium and visible light is filtered. In another aspect, the system can be activated by a trigger from the individual, whether the individual has knowledge of the trigger or not. The trigger can be a transistor or sensor integrated in the system that is capable of activating the system. Such triggers can be a thermal sensor, motion sensor, photosensor and other like sensors.

[0014] The system can also be designed to be of a small size. For example, in one aspect the light source, the imager device, and the image processing module can collectively have a size of less than about 160 cubic centimeters. In another aspect, the light source, the imager device, and the image processing module can collectively have a size of less than about 16 cubic centimeters. In yet another aspect, the imager device can have an optical format of about 1/7 inches.

[0015] It is also contemplated that the present systems and devices can be utilized in a variety of other systems, devices, and situations. For example, in one aspect the present system can be integrated into an electronic device. While any electronic device is contemplated, non-limiting examples can include a mobile smart phone, a cellular phone, a laptop computer, a tablet computer, other personal electronic devices and the like. Various situations are also contemplated wherein such integration can be useful. For example, in one aspect such an electronic device can provide positive

identification of an individual in order to unlock the electronic device. In another aspect, positive identification of the individual can be used to verify the individual in a financial transaction. In another aspect, the positive identification can be used to determine citizenship of the individual or to verify passport or license status.

[0016] The present disclosure additionally provides methods of identifying an individual. In one aspect, such a method can include emitting infrared electromagnetic radiation having at least one wavelength of from about 700 nm to about 1200 nm toward the individual, receiving the infrared electromagnetic radiation reflected from the individual into an imager device to generate an electronic representation of the individual, processing the electronic representation into an individual representation having at least one substantially unique identification trait, and using the at least one substantially unique identification trait to identify the individual. The imager device can include a semiconductor device layer having a thickness of less than about 10 microns, at least two doped regions forming a junction, and a textured region positioned to interact with the electromagnetic radiation. The imaging device can have an external quantum efficiency of at least about 33% for electromagnetic radiation having at least one wavelength of greater than 800 nm.

[0017] In one specific aspect, the at least one substantially unique identification trait can include an electronic representation of an iris of the individual sufficient to identify the individual. In one specific aspect, the electronic representation of the iris can be captured by the imager device at a distance of from about 0.5 meters to about 15 meters from the individual. In yet another specific aspect, the electronic representation of the iris can be captured by the imager device at a distance of from about 2 meters to about 10 meters from the individual. In a further specific aspect, the electronic representation of the iris can be captured at a distance of greater than 2 meters from the imager device to the individual using the infrared electromagnetic radiation having a wavelength of at least 940 nm and an intensity that is below 10,000 mW/mm²/steradian.

[0018] In yet another aspect, emitting infrared electromagnetic radiation can further include emitting infrared electromagnetic radiation from at least two active light sources, each emitting at distinct peak emission wavelengths. In such cases, electronic representations from each active light source can be processed into individual representations each having at least one substantially unique identification trait, and each individual representation can then be compared with one another to verify identification results of the individual.

[0019] In one aspect, capturing the electronic representation by the imager device can be accomplished by a global electronic shutter mechanism. In one specific aspect, the global electronic shutter can be operated with an integration time of from about 0.1 ms to about 1 ms. In another specific aspect, the individual can be moving with respect to the imager device and the integration time is sufficient to capture the electronic representation with sufficient detail to identify the at least one substantially unique identification trait.

[0020] In another aspect, the method can include comparing the at least one substantially unique identification trait with a known identification trait to facilitate identification of the individual. A variety of known identification traits are contemplated, non-limiting examples of which can include

facial features, iris features, thermal signatures, and the like, including combinations thereof. Furthermore, in one aspect comparing the at least one substantially unique identification trait further includes comparing the at least one substantially unique identification trait against a plurality of known identification traits.

[0021] In yet another aspect, the individual representation can be a facial representation, and the facial representation can be analyzed to locate a specific facial feature and the imager device can be panned and/or zoomed to image the specific facial feature or iris feature.

[0022] In a further aspect, the method can include moving the emitted infrared electromagnetic radiation and/or the imager device relative to movements of the individual in order to track the individual during receiving of the infrared electromagnetic radiation.

[0023] In yet another aspect, the method can further include receiving the electronic representation, selecting a portion of the electronic representation, zooming the imager device to substantially correspond to the portion of the electronic representation and generating a secondary electronic representation of the individual, and processing the secondary electronic representation into a secondary individual representation having at least one substantially unique identification trait.

[0024] In a further aspect, an electronic device having an integrated user authorization system is provided, wherein the user authorization system includes an imager device including a semiconductor device layer having a thickness of less than about 10 microns, at least two doped regions forming a junction, and a textured region positioned to interact with the electromagnetic radiation, wherein the imaging device has an external quantum efficiency of at least about 33% for electromagnetic radiation having at least one wavelength of greater than 800 nm. The imager device is positioned to capture an electronic representation of an identification trait of a user of the device, wherein the imager device is operable to at least periodically capture the electronic representation. The system can further include a storage register operable to store a known identification trait of an authorized user, and an analysis module electrically coupled to the imager device and the storage register, the analysis module being operable to compare the electronic representation of the identification trait to the known identification trait to verify that the user is the authorized user. In another aspect, the system can further include a light source operable to emit electromagnetic radiation having at least one wavelength of from about 700 nm to about 1200 nm toward the user. In yet another aspect, the analysis module and the imager device can be integrated monolithically together separate from the CPU of the electronic device. It should be noted that the analysis module can be physically separate from the imager device and operate independently from the CPU of the electronic device. In a further aspect, the imager device can be operable to continuously verify the user is the authorized user. In yet a further aspect, the system can include a switch to toggle the imager device between infrared light capture and visible light capture modes. Various switches are contemplated herein, for example, a transistor, an infrared or color filter and others known by those skilled in the art.

BRIEF DESCRIPTION OF THE DRAWINGS

[0025] For a fuller understanding of the nature and advantage of the present invention, reference is being made to the following detailed description of preferred embodiments and in connection with the accompanying drawings, in which:

[0026] FIG. 1 is a representation of a system for identifying an individual in accordance with one aspect of the present disclosure.

[0027] FIG. 2 is a schematic view of an imager device in accordance with another aspect of the present disclosure.

[0028] FIG. 3 is a graphical representation of the absorption characteristics of a fast (or thin) photodetector device based on standard silicon compared to the absorption characteristics of a photodetecting device based on silicon but having a textured region in accordance with another aspect of the present disclosure.

[0029] FIG. 4 is a schematic view of a photosensitive device in accordance with another aspect of the present disclosure.

[0030] FIG. 5 is a schematic view of a photosensitive array device in accordance with another aspect of the present disclosure.

[0031] FIG. 6 is a schematic diagram of a six transistor imager in accordance with another aspect of the present disclosure.

[0032] FIG. 7a is a photograph showing an iris captured with an photoimager having a rolling shutter in accordance with another aspect of the present disclosure.

[0033] FIG. 7b is a photograph showing an iris captured with an photoimager having a global shutter in accordance with another aspect of the present disclosure.

[0034] FIG. 8 is an illustration of a time of flight measurement in accordance with another aspect of the present disclosure.

[0035] FIG. 9a is a schematic view of a pixel configuration for a photoimager array in accordance with another aspect of the present disclosure.

[0036] FIG. 9b is a schematic view of a pixel configuration for a photoimager array in accordance with another aspect of the present disclosure.

[0037] FIG. 9c is a schematic view of a pixel configuration for a photoimager array in accordance with another aspect of the present disclosure.

[0038] FIG. 10 is a schematic diagram of an eleven transistor imager in accordance with another aspect of the present disclosure.

[0039] FIG. 11 is a schematic view of a photosensitive device comprising a bolometer in accordance with another aspect of the present disclosure.

[0040] FIG. 12 is a representation of an integrated system for identifying an individual in accordance with one aspect of the present disclosure.

[0041] FIG. 13 is a flow diagram of a method in accordance with another aspect of the present disclosure.

DETAILED DESCRIPTION

[0042] Before the present disclosure is described herein, it is to be understood that this disclosure is not limited to the particular structures, process steps, or materials disclosed herein, but is extended to equivalents thereof as would be recognized by those ordinarily skilled in the relevant arts. It should also be understood that terminology employed herein

is used for the purpose of describing particular embodiments only and is not intended to be limiting.

Definitions

[0043] The following terminology will be used in accordance with the definitions set forth below.

[0044] It should be noted that, as used in this specification and the appended claims, the singular forms “a,” and, “the” include plural referents unless the context clearly dictates otherwise. Thus, for example, reference to “a dopant” includes one or more of such dopants and reference to “the layer” includes reference to one or more of such layers.

[0045] As used herein, “quantum efficiency” (QE) is defined as the percentage of photons incident on an optoelectronic device that are converted into electrons. External QE (EQE) is defined as the current obtained outside of the device per incoming photon. As such, EQE therefore depends on both the absorption of photons and the collection of charges. The EQE is lower than the QE due to recombination effects and optical losses (e.g. transmission and reflection losses).

[0046] As used herein, the terms “electromagnetic radiation” and “light” can be used interchangeably, and can represent wavelengths across a broad range, including visible wavelengths (approximately 350 nm to 800 nm) and non-visible wavelengths (longer than about 800 nm or shorter than 350 nm). The infrared spectrum is often described as including a near infrared portion of the spectrum including wavelengths of approximately 800 to 1300 nm, a short wave infrared portion of the spectrum including wavelengths of approximately 1300 nm to 3 micrometers, and a mid to long wave infrared (or thermal infrared) portion of the spectrum including wavelengths greater than about 3 micrometers up to about 30 micrometers. These are generally and collectively referred to herein as “infrared” portions of the electromagnetic spectrum unless otherwise noted.

[0047] As used herein, “response time” refers to the rise time or fall time of a detector device. In one aspect, “rise time” is the time difference between the 10% point and the 90% point of the peak amplitude output on the leading edge of the electrical signal generated by the interaction of light with the device. “Fall time” is measured as the time difference between the 90% point and the 10% point of the trailing edge of the electrical signal. In some aspects, fall time can be referred to as the decay time.

[0048] As used herein, “shutter speed” refers to the time duration of a camera’s shutter remain open while an image is captured. The shutter speed directly proportional to the exposure time, i.e. the duration of light reaching the image sensor. In other words, the shutter speed controls the amount of light that reaches the photosensitive imager. The slower the shutter speed, the longer the exposure time. Shutter speeds are commonly expressed in seconds and fractions of seconds. For example, 4, 2, 1, $\frac{1}{2}$, $\frac{1}{4}$, $\frac{1}{8}$, $\frac{1}{15}$, $\frac{1}{30}$, $\frac{1}{60}$, $\frac{1}{125}$, $\frac{1}{250}$, $\frac{1}{500}$, $\frac{1}{1000}$, $\frac{1}{2000}$, $\frac{1}{4000}$, $\frac{1}{8000}$. Notably, each speed increment halves the amount of light incident upon the imager.

[0049] As used herein, the term “textured region” refers to a surface having a topology with nano- to micron-sized surface variations. Such a surface topology can be formed by any appropriate technique, including, without limitation, irradiation of a laser pulse or laser pulses, chemical etching, lithographic patterning, interference of multiple simultaneous laser pulses, reactive ion etching, and the like. While the

characteristics of such a surface can be variable depending on the materials and techniques employed, in one aspect such a surface can be several hundred nanometers thick and made up of nanocrystallites (e.g. from about 10 to about 50 nanometers) and nanopores. In another aspect, such a surface can include micron-sized structures (e.g. about 0.5 μm to about 60 μm). In yet another aspect, the surface can include nano-sized and/or micron-sized structures from about 5 nm and about 500 μm . It should be mentioned that the textured region can be ordered or disordered.

[0050] As used herein, the terms “surface modifying” and “surface modification” refer to the altering of a surface of a semiconductor material using a variety of surface modification techniques. Non-limiting examples of such techniques include plasma etching, reactive ion etching, porous silicon etching, lasing, chemical etching (e.g. anisotropic etching, isotropic etching), nanoimprinting, material deposition, selective epitaxial growth, and the like, including combinations thereof. In one specific aspect, surface modification can include processes using primarily laser radiation or laser radiation in combination with a dopant, whereby the laser radiation facilitates the incorporation of the dopant into a surface of the semiconductor material. Accordingly, in one aspect surface modification includes doping of a substrate such as a semiconductor material.

[0051] As used herein, the term “target region” refers to an area of a substrate that is intended to be doped or surface modified. The target region of the substrate can vary as the surface modifying process progresses. For example, after a first target region is doped or surface modified, a second target region may be selected on the same substrate.

[0052] As used herein, the term “fluence” refers to the amount of energy from a single pulse of laser radiation that passes through a unit area. In other words, “fluence” can be described as the energy surface density of one laser pulse.

[0053] As used herein, the term “detection” refers to the sensing, absorption, and/or collection of electromagnetic radiation.

[0054] As used herein, the term “scene radiance” refers to the areal density of light impinging on a known area or scene.

[0055] As used herein, the term “substantially” refers to the complete or nearly complete extent or degree of an action, characteristic, property, state, structure, item, or result. For example, an object that is “substantially” enclosed would mean that the object is either completely enclosed or nearly completely enclosed. The exact allowable degree of deviation from absolute completeness may in some cases depend on the specific context. However, generally speaking the nearness of completion will be so as to have the same overall result as if absolute and total completion were obtained. The use of “substantially” is equally applicable when used in a negative connotation to refer to the complete or near complete lack of an action, characteristic, property, state, structure, item, or result. For example, a composition that is “substantially free of” particles would either completely lack particles, or so nearly completely lack particles that the effect would be the same as if it completely lacked particles. In other words, a composition that is “substantially free of” an ingredient or element may still actually contain such item as long as there is no measurable effect thereof.

[0056] As used herein, the term “about” is used to provide flexibility to a numerical range endpoint by providing that a given value may be “a little above” or “a little below” the endpoint.

[0057] As used herein, a plurality of items, structural elements, compositional elements, and/or materials may be presented in a common list for convenience. However, these lists should be construed as though each member of the list is individually identified as a separate and unique member. Thus, no individual member of such list should be construed as a de facto equivalent of any other member of the same list solely based on their presentation in a common group without indications to the contrary.

[0058] Concentrations, amounts, and other numerical data may be expressed or presented herein in a range format. It is to be understood that such a range format is used merely for convenience and brevity and thus should be interpreted flexibly to include not only the numerical values explicitly recited as the limits of the range, but also to include all the individual numerical values or sub-ranges encompassed within that range as if each numerical value and sub-range is explicitly recited. As an illustration, a numerical range of “about 1 to about 5” should be interpreted to include not only the explicitly recited values of about 1 to about 5, but also include individual values and sub-ranges within the indicated range. Thus, included in this numerical range are individual values such as 2, 3, and 4 and sub-ranges such as from 1-3, from 2-4, and from 3-5, etc., as well as 1, 2, 3, 4, and 5, individually.

[0059] This same principle applies to ranges reciting only one numerical value as a minimum or a maximum. Furthermore, such an interpretation should apply regardless of the breadth of the range or the characteristics being described.

[0060] The Disclosure Security has generally become a top priority for many businesses, communities, governments, and the like. One key component in establishing effective security is the rapid identification of individuals. For example, implementation of biometric scanning procedures in major thoroughfares such as airports, major cities, and the like can facilitate the identification and tracking of individuals for the safety of the populace as well as, in some cases, the safety of the individual being identified and tracked. As one example, such a system can be utilized to identify abducted or runaway children. In other cases, fugitives and suspected criminals can be located and apprehended. Also, such systems can be useful for identifying authorized users and allowing access for authorized users for financial transactions, personal electronic devices that can reduce the incidence of voter fraud, financial fraud, other forms of identity theft, and the like.

[0061] As has been described, one problem inherent to biometric systems imaging facial and ocular features is interference due to pigmentation. To avoid this potential interference, a biometric imaging device capturing light wavelengths in the range of 800 nm to 1300 nm can be used. For electromagnetic radiation in this wavelength range pigmentation is substantially transparent, and therefore electromagnetic photons pass freely through the pigment and reflect off of structural elements of interest for the identification. In the eye, for example, near infrared electromagnetic photons pass through the iris pigment and reflect off of iris ligament structures.

[0062] Conventional imagers, however, including both CCDs and CMOS image sensors, are based on silicon

photodetectors and have very low sensitivity to near infrared light in the wavelength range of interest. As such, in many cases these systems are limited to applications where the low sensitivity and image capture speed limitations are not an issue. When attempting to capture an iris signature from a distance and/or with a short integration time, IR light needs to be greatly increased in intensity to compensate for the poor IR sensitivity of traditional imagers. High intensity IR can be damaging to ocular tissue and potentially may cause other negative side effects.

[0063] The present disclosure provides an efficient biometric device that can operate in low light conditions with good signal to noise ratio and high quantum efficiencies in the visible and infrared (IR) spectrum. Using an IR light source, as opposed to purely visible light, the present system can image the textured patterns of the iris, remove existing light variations, and reduce pattern interference from corneal reflections, thereby capturing more precise iris information.

[0064] In one aspect, as is shown in FIG. 1 for example, a system for identifying an individual can include at least one active light source **102** capable of emitting electromagnetic radiation **104** having at least one wavelength of from about 700 nm to about 1200 nm and an imager device **106** positioned to receive the electromagnetic radiation upon reflection **108** from an individual **110** to generate an electronic representation of the individual. An image processing module **112** can be functionally coupled to the imager device **106** to receive the electronic representation. The image processing module **112** functions to process the electronic representation, using known algorithms to those skilled in the art, into an individual representation having at least one substantially unique identification trait. This substantially unique identification trait is used to identify the individual **110**. Additionally, it is noted that such a system can be utilized in cooperative as well as non-cooperative identification situations.

[0065] FIG. 2 shows one exemplary embodiment of an imager device that is capable of operation in low light conditions with good signal to noise ratio and high quantum efficiencies in the visible and IR light spectrum. The imager device **200** can include a semiconductor device layer **202** having a device layer with a thickness of less than about 10 microns, at least two doped regions **204**, **206** forming a junction, and a textured region **208** positioned to interact with incoming electromagnetic radiation **210**. Numerous configurations are contemplated, and any type of junction configuration is considered to be within the present scope. For example, the first and second doped regions can be distinct from one another, contacting one another, overlapping one another, etc. In some cases, an intrinsic region can be located at least partially between the first and second doped regions. In some aspects, the semiconductor device layer can be less than about 50 microns thick. Additionally, in some aspects the semiconductor device layer can be disposed on a bulk semiconductor layer or semiconductor support layer.

[0066] The textured region **208** is shown located on a side of the semiconductor device layer **202** that is opposite to the first doped region **204** and the second doped region **206**. In this case, electromagnetic radiation that passes through the semiconductor device layer **202** to contact the textured region **208** can be reflected back through the semiconductor device layer, thus effectively increasing the absorption path length of the semiconductor material. The textured region

can be associated with an entire surface of the semiconductor material or only a portion thereof. Additionally, in some aspects the textured region can be specifically positioned to maximize the absorption path length of the semiconductor material. In other aspects, a third doping can be included near the textured region to improve the collection of carriers generated near the textured region.

[0067] The imager device can have a semiconductor device layer with a thickness of less than about 10 microns and an external quantum efficiency of at least about 33% for electromagnetic radiation having at least one wavelength of greater than 800 nm. In another aspect, the imager device can have a response time of from about 0.1 ms to about 1 ms and an external quantum efficiency of at least about 33% for electromagnetic radiation having at least one wavelength greater than about 800 nm. In another aspect, the response time can be from about 0.1 ms to about 16 ms. Other thicknesses of device layers are additionally contemplated. In one aspect, for example, the device layer thickness can be less than 50 microns. In another aspect, the device layer thickness can be less than 5 microns. In yet another aspect, the device layer thickness can be less than 1 micron. A lower limit for thickness of the device layer can be any thickness that allows functionality of the device. In one aspect, however, the device layer can be at least 10 nm thick. In another aspect, the device layer can be at least 100 nm thick. In yet another aspect, the device layer can be at least 500 nm thick. Additionally, in another aspect, the imager device can have an external quantum efficiency of at least about 23% for electromagnetic radiation having at least one wavelength greater than about 850 nm. In yet another aspect, the imager device can have an external quantum efficiency of at least about 11% for electromagnetic radiation having at least one wavelength greater than about 940 nm. In another aspect, the imager device can have a response time of from about 0.1 ms to about 1 ms and an external quantum efficiency of at least about 11% for electromagnetic radiation having at least one wavelength greater than about 940 nm.

[0068] In yet another aspect, the imager device can have an external quantum efficiency of at least about 46% for electromagnetic radiation having at least one wavelength of greater than 800 nm. In another aspect, the imager device can have a response time of from about 0.1 ms to about 1 ms and an external quantum efficiency of at least about 46% for electromagnetic radiation having at least one wavelength greater than about 800 nm. Additionally, in another aspect, the imager device can have a semiconductor device layer having a thickness of less than 10 microns, and the imager can have an external quantum efficiency of at least about 32% for electromagnetic radiation having at least one wavelength greater than about 850 nm. In still another aspect, the imager device can have a semiconductor device layer having a thickness of less than 10 microns, and the imager can have an external quantum efficiency of at least 50% or at least 60% for electromagnetic radiation having at least one wavelength greater than about 850 nm. In yet another aspect, the imager device can have an external quantum efficiency of at least about 15% for electromagnetic radiation having at least one wavelength greater than about 940 nm. In another aspect, the imager device can have a response time of from about 0.1 ms to about 1 ms and an external quantum efficiency of at least about 15% for electromagnetic radiation having at least one wavelength greater than about 940 nm. Further details regarding such photosensitive devices

have been described in U.S. application Ser. No. 13/164,630, filed on Jun. 20, 2011, which is incorporated herein by reference in its entirety.

[0069] It should be noted that, while the device shown in FIG. 2 has a frontside illuminated architecture, backside illuminated architectures are also contemplated and are considered to be within the present scope. Additionally, whether frontside illuminated or backside illuminated, the textured region 208 can be positioned on a side of the semiconductor device layer 202 opposite the incoming electromagnetic radiation 210 as shown. The textured region can also be positioned on a side of the semiconductor device layer adjacent the incoming electromagnetic radiation (not shown). In other words, in this case the electromagnetic radiation would contact the textured region prior to passing into the semiconductor device layer. Additionally, it is contemplated that the textured region can be positioned on both an opposite side and an adjacent side of the semiconductor device layer.

[0070] The present imaging device can be utilized to capture an electronic representation that is capable of being used to identify an individual at short distances as well as long distances. The device can capture the electronic representation at short distances such as, for example, from about 2 cm or less to about 10 cm, or up to 50 cm, or up to 0.5 m. The device can also capture the electronic representation at from short distances to long distances such as, for example, up to 1 m, up to 3 m, up to 6 m, up to 10 m, or up to 15 m or more.

[0071] The semiconductor utilized to construct the imager can be any useful semiconductor material from which such an imager can be made having the properties described herein. In one aspect, however, the semiconductor device layer is silicon. It is noted, however, that silicon photodetectors have limited detectability of IR wavelengths of light, particularly for thin film silicon devices. Traditional silicon materials require substantial absorption depths in order to detect photons having wavelengths longer than about 700 nm. While visible light can be readily absorbed in the first few microns of a silicon layer, absorption of longer wavelengths (e.g. 900 nm) in silicon at a thin wafer depth (e.g. approximately 100 μm) is poor if at all. The present imager devices can increase the electromagnetic radiation absorption range of silicon, thus allowing the absorption of visible and IR light even at shallow depths and in silicon thin films.

[0072] Returning to FIG. 2, for example, the textured region 208 can increase the absorption, increase the external quantum efficiency, and decrease response times, particularly in the infrared wavelengths. Such unique and novel devices can allow for fast shutter speeds thereby capturing images of moving objects in the visible and infrared spectrums. Such an increased sensitivity in a silicon-based device can thus reduce processing cost of photodetectors, reduce the power needed in light sources, increase the depth resolution in 3D types imaging, and improve the biometric measurements of an individual.

[0073] FIG. 3 shows an absorption/responsivity graph where the dashed line 302 represents the absorption characteristics of a photodiode based on a traditional standard fast silicon device, and the solid line 304 represents the absorption characteristics of a silicon-based photodiode device but including a textured region. Notably, the absorption of a standard fast silicon imager in the infrared (i.e. the 800 nm to 1200 nm region) results in relatively low respon-

sivity compared to the imager device with the textured region. It is noted that an imager is a collection of multiple photodiodes.

[0074] While it is contemplated that the present system can include optics for increasing the capture distance between the device and the individual, the imager device having the textured region allows the system to function at low IR light intensity levels even at such long distances. This reduces energy expenditure and thermal management issues, as well as potentially decreasing side effects that can result from high intensity IR light. In one aspect, for example, the imager device can capture the electronic representation of an individual with sufficient detail to identify a substantially unique identification trait using electromagnetic radiation emitted from the active light source having at least one wavelength of from about 700 nm to about 1200 nm and having a scene radiance impinging on the individual at 3 meters that is at least 0.1 mW/mm². In another aspect, the imager device can capture the electronic representation of an individual with sufficient detail to identify a substantially unique identification trait using electromagnetic radiation emitted from the active light source having at least one wavelength of from about 800 nm to about 1000 nm and having a scene radiance impinging on the individual at 3 meters that is from about 0.1 mW/mm² to about 100 mW/mm². In another aspect the imager device can capture the electronic representation of an individual with sufficient detail to identify a substantially unique identification trait using electromagnetic radiation emitted from the active light source having at least one wavelength of from about 800 nm to about 1000 nm and having a scene radiance impinging on the individual at 3 meters that is from about 1 mW/mm² to about 10 mW/mm². In yet another aspect, at distances of greater than 2 meters the electromagnetic radiation having a wavelength of at least 940 nm and should have optical power below the eye damage threshold of 10,000 mW/mm²/steradian. It should be noted that in one aspect the substantially unique identification trait is an iris pattern of the individual.

[0075] As has been described, in some aspects the thickness of the silicon material in the device can dictate the responsivity and response time. Standard silicon devices need to be thick, i.e. greater than 100 μm in order to detect wavelengths in the infrared spectrum, and such detection with thick devices results in a slow response and high dark current. The textured region is positioned to interact with electromagnetic radiation to increase the absorption of infrared light in a device, thereby improving the infrared responsivity while allowing for fast operation. Diffuse scattering and reflection can result in increased path lengths for absorption, particularly if combined with total internal reflection, resulting in large improvements of responsivity in the infrared for silicon photodiodes, photodetectors, photodiode arrays, imagers, and the like. Because of the increased path lengths for absorption, thinner silicon materials can be used to absorb electromagnetic radiation up into the infrared regions. One advantage of thinner silicon material devices is that charge carriers are more quickly swept from the device, thus decreasing the response time. Conversely, thick silicon material devices sweep charge carriers therefrom more slowly, at least in part due to diffusion.

[0076] It is noted, however, that the silicon device layer can be of any thickness that allows electromagnetic radiation detection and conversion functionality, and thus any such thickness of silicon device layer is considered to be within

the present scope. With that being said, thin silicon layer materials can be particularly beneficial in decreasing the response time and/or the capacitance of the device. As has been described, charge carriers can be more quickly swept from thinner silicon material layers as compared to thicker silicon material layers. The thinner the silicon, the less material the electron/holes have to traverse in order to be collected, and the lower the probability of a generated charge carrier encountering a defect that could trap or slow the collection of the carrier. Thus one objective to implementing a fast photo response is to utilize a thin silicon material for the semiconductor device layer of the imager. Such a device can be nearly depleted of charge carriers by the built in potential of the photodiode and any applied bias to provide for a fast collection of the photo generated carriers by drift in an electric field. Charge carriers remaining in any undepleted region of the photodiode are collected by diffusion transport, which is slower than drift transport. For this reason, it can be desirable to have the thickness of any region where diffusion may dominate to be much thinner than the depleted drift regions. In silicon materials having the proper doping provides a depletion region of about 10 μm with no applied bias. As such, in some aspects it can be useful to utilize a silicon material layer having a thickness of less than about 100 μm, less than about 10 μm or less than about 5 μm. In another aspect, the silicon material can have a thickness and substrate doping concentration such that an applied bias generates an electrical field sufficient for saturation velocity of the charge carriers. It should be noted that operating a photodiode, as disclosed herein, at a zero bias can result in low noise but at a longer response time. When bias is applied however, the dark current is increased, resulting in higher noise, but with a decreased response time. The increased dark current can be compensated if the incident radiation signal is strong. The amount of dark current increase can be minimized, however, with a thinner device layer.

[0077] The semiconductor device layer in general can be of any thickness that allows electromagnetic radiation detection and conversion functionality, and thus any such thickness of semiconductor material is considered to be within the present scope. In some aspects, the textured region increases the efficiency of the device such that the semiconductor device layer can be thinner than has previously been possible. Decreasing the thickness of the semiconductor device layer reduces the amount of semiconductor material required to make such a device. In one aspect, for example, the semiconductor device layer has a thickness of from about 500 nm to about 50 μm. In another aspect, the semiconductor device layer has a thickness of less than or equal to about 100 μm. In yet another aspect, the semiconductor device layer has a thickness of from about 500 nm to about 20 μm. In another aspect, the semiconductor device layer has a thickness of from about 500 nm to about 10 μm. In a further aspect, the semiconductor device layer can have a thickness of from about 500 nm to about 50 μm. In yet a further aspect, the semiconductor device layer can have a thickness of from about 500 nm to about 2 μm. In other aspect the semiconductor device layer can have a thickness of less than 10 microns, 5 microns, or 1 microns.

[0078] In one aspect a silicon semiconductor device layer has a thickness of from about 100 nm to about 100 μm. In another aspect, the silicon material has a thickness of from about 0.5 μm to about 50 μm. In yet another aspect, the

silicon material has a thickness of from about 5 μm to about 10 μm . In a further aspect, the silicon material has a thickness of from about 1 μm to about 5 μm .

[0079] As has been described, the response time of a photosensitive imaging device is limited by the transit time of the photo generated carriers across the thickness of the device layer. As further explanation, the RC time constant of the load resistance, (R) and the capacitance (C) of the entire electronic device structure can be kept less than this transit time by using small load resistors and keeping the capacitance of the photodiodes small by limiting the doping density of the silicon material and area of the photodiodes. For example, photodiodes doped at $10^{15}/\text{cm}^3$ can have a capacitance that may be $10 \text{ nF}/\text{cm}^2$ without any applied bias. Small area photodiodes with 50 ohm load resistors can have very fast RC time constants. A photodiode with an area of 0.01 cm^2 can have a RC time constant of 0.5 nanoseconds. Given that the response time will be limited by the maximum charge carrier transit time across the photodiode, then diffusion rates can place an upper limit on the response time for photodiodes of different thickness. For example, if the photodiodes have a thickness of less than $d=100 \mu\text{m}$, then the diffusion transit time can be calculated by Equation (II) below, where D is the diffusion coefficient for electrons.

$$\frac{d^2}{2D} \quad (\text{II})$$

The response time is bound by an upper limit of 2 μs . For light having a wavelength of about 900 nm, only about 35% is absorbed in the first pass or a device thinner than 100 μm and approximately 30% is reflected at the first surface, thereby giving a responsivity on the order 10% or 0.1 A/W. The responsivity, R, can be increased at least five fold by using multiple internal reflections to achieve a value of $R=0.5 \text{ A/W}$.

[0080] Thus, the devices of the present disclosure increase the absorption path length of silicon materials by increasing the absorption path length for longer wavelengths as compared to traditional silicon devices. The absorption depth in silicon photodetectors is the depth into silicon at which the radiation intensity is reduced to about 36% of the value at the surface of the silicon material. The increased absorption path length results in an apparent reduction in the absorption depth, or a reduced apparent or effective absorption depth. For example, the effective absorption depth of silicon can be reduced such that longer wavelengths can be absorbed at depths of less than or equal to about 100 μm . By increasing the absorption path length, such devices are able to absorb longer wavelengths (e.g. $>1000 \text{ nm}$ for silicon) within a thin semiconductor material. In addition to decreasing the effective absorption depth, the response time can be decreased using thinner semiconductor materials.

[0081] In one aspect, a photodiode can have a thickness of less than about $d=10 \mu\text{m}$. Using equation (I) above, the resultant upper response time limit is about 20 ns. For light having a wavelength of about 700 nm with about 33% absorbed in the first pass and about 30% being reflected at the first surface, the responsivity can be on the order 10% or 0.3 Ampere/Watt. The responsivity, R, can be increased at least two fold by using multiple internal reflections as described herein to achieve a value of $R=0.6 \text{ A/W}$.

[0082] In one aspect, for example, an imager device has a response time of from about 0.1 ms to about 1 ms. In another aspect, an imager device has a responsivity of from about 0.4 A/W to about 0.55 A/W for at least one wavelength of from about 800 nm to about 1200 nm relative to standard silicon. In yet another aspect, an imager device has a responsivity of from about 0.1 A/W to about 0.55 A/W for at least one wavelength of from about 1000 nm to about 1200 nm relative to standard silicon. In another aspect, the optoelectronic device has an increased external quantum efficiency of at least 10% for at least one wavelength of from about 550 nm to about 1200 nm relative to a silicon device with comparable thickness and response time.

[0083] As has been described, photosensitive imaging devices according to aspects of the present disclosure can exhibit lower levels of dark current as compared to traditional devices. Although a variety of reasons are possible, one exemplary reason may be that a thinner silicon material layer can have fewer crystalline defects responsible for the generation of dark current. In one aspect, for example, the dark current of an photosensing imaging device during operation is from about $100 \text{ pA}/\text{cm}^2$ to about $10 \text{ nA}/\text{cm}^2$. In another aspect, the maximum dark current of an imaging device during operation is less than about $1 \text{ nA}/\text{cm}^2$.

[0084] Accordingly, imager devices according to aspects of the present disclosure provide, among other things, enhanced response in the infrared light portion of the optical spectrum and improved response and quantum efficiency in converting electromagnetic radiation to electrical signals. As such, high quantum efficiencies and increase response times can be obtained in the infrared for devices thinner than about 100 μm . In other words, the sensitivity and response are higher than that found in thicker devices at infrared wavelengths.

[0085] In addition to silicon, other semiconductor materials are contemplated for use in the imager devices of the present disclosure. Non-limiting examples of such semiconductor materials can include group IV materials, compounds and alloys comprised of materials from groups II and VI, compounds and alloys comprised of materials from groups III and V, and combinations thereof. More specifically, exemplary group IV materials can include silicon, carbon (e.g. diamond), germanium, and combinations thereof. Various exemplary combinations of group IV materials can include silicon carbide (SiC) and silicon germanium (SiGe). Exemplary silicon materials, for example, can include amorphous silicon (a-Si), microcrystalline silicon, multicrystalline silicon, and monocrystalline silicon, as well as other crystal types. In another aspect, the semiconductor material can include at least one of silicon, carbon, germanium, aluminum nitride, gallium nitride, indium gallium arsenide, aluminum gallium arsenide, and combinations thereof.

[0086] Exemplary combinations of group II-VI materials can include cadmium selenide (CdSe), cadmium sulfide (CdS), cadmium telluride (CdTe), zinc oxide (ZnO), zinc selenide (ZnSe), zinc sulfide (ZnS), zinc telluride (ZnTe), cadmium zinc telluride (CdZnTe, CZT), mercury cadmium telluride (HgCdTe), mercury zinc telluride (HgZnTe), mercury zinc selenide (HgZnSe), and combinations thereof.

[0087] Exemplary combinations of group III-V materials can include aluminum antimonide (AlSb), aluminum arsenide (AlAs), aluminum nitride (AlN), aluminum phosphide (AlP), boron nitride (BN), boron phosphide (BP), boron arsenide (BAs), gallium antimonide (GaSb), gallium

arsenide (GaAs), gallium nitride (GaN), gallium phosphide (GaP), indium antimonide (InSb), indium arsenide (InAs), indium nitride (InN), indium phosphide (InP), aluminum gallium arsenide (AlGaAs, $\text{Al}_x\text{Ga}_{1-x}\text{As}$), indium gallium arsenide (InGaAs, $\text{In}_x\text{Ga}_{1-x}\text{As}$), indium gallium phosphide (InGaP), aluminum indium arsenide (AlInAs), aluminum indium antimonide (AlInSb), gallium arsenide nitride (GaAsN), gallium arsenide phosphide (GaAsP), aluminum gallium nitride (AlGaN), aluminum gallium phosphide (AlGaP), indium gallium nitride (InGaN), indium arsenide antimonide (InAsSb), indium gallium antimonide (InGaSb), aluminum gallium indium phosphide (AlGaInP), aluminum gallium arsenide phosphide (AlGaAsP), indium gallium arsenide phosphide (InGaAsP), aluminum indium arsenide phosphide (AlInAsP), aluminum gallium arsenide nitride (AlGaAsN), indium gallium arsenide nitride (InGaAsN), indium aluminum arsenide nitride (InAlAsN), gallium arsenide antimonide nitride (GaAsSbN), gallium indium nitride arsenide antimonide (GaInNAsSb), gallium indium arsenide antimonide phosphide (GaInAsSbP), and combinations thereof.

[0088] Additionally, various types of semiconductor materials are contemplated, and any such material that can be incorporated into an electromagnetic radiation detection device is considered to be within the present scope. In one aspect, for example, the semiconductor material is monocrystalline. In another aspect, the semiconductor material is multicrystalline. In yet another aspect, the semiconductor material is microcrystalline. It is also contemplated that the semiconductor material can be amorphous. Specific nonlimiting examples include amorphous silicon or amorphous selenium.

[0089] The semiconductor materials of the present disclosure can also be made using a variety of manufacturing processes. In some cases the manufacturing procedures can affect the efficiency of the device, and may be taken into account in achieving a desired result. Exemplary manufacturing processes can include Czochralski (Cz) processes, magnetic Czochralski (mCz) processes, Float Zone (FZ) processes, epitaxial growth or deposition processes, and the like. It is contemplated that the semiconductor materials used in the present invention can be a combination of monocrystalline material with epitaxially grown layers formed thereon.

[0090] A variety of dopant materials are contemplated for the formation of the multiple doped regions, the textured region, or any other doped portion of the imager device, and any such dopant that can be used in such processes is considered to be within the present scope. It should be noted that the particular dopant utilized can vary depending on the material being doped, as well as the intended use of the resulting material.

[0091] A dopant can be either electron donating or hole donating. In one aspect, non-limiting examples of dopants can include S, F, B, P, N, As, Se, Te, Ge, Ar, Ga, In, Sb, and combinations thereof. It should be noted that the scope of dopants should include, not only the dopants themselves, but also materials in forms that deliver such dopants (i.e. dopant carriers). For example, S dopants includes not only S, but also any material capable being used to dope S into the target region, such as, for example, H_2S , SF_6 , SO_2 , and the like, including combinations thereof. In one specific aspect, the dopant can be S. Sulfur can be present at an ion dosage level of between about 5×10^{14} and about 1×10^{16} ions/cm². Non-

limiting examples of fluorine-containing compounds can include ClF_3 , PF_5 , F_2SF_6 , BF_3 , GeF_4 , WF_6 , SiF_4 , HF, CF_4 , CHF_3 , CH_2F_2 , CH_3F , C_2F_6 , C_2HF_5 , C_3F_8 , C_4F_8 , NF_3 , and the like, including combinations thereof. Non-limiting examples of boron-containing compounds can include $\text{B}(\text{CH}_3)_3$, BF_3 , BCl_3 , BN, $\text{C}_2\text{B}_{10}\text{H}_{12}$, borosilica, B_2H_6 , and the like, including combinations thereof. Non-limiting examples of phosphorous-containing compounds can include PF_5 , PH_3 , and the like, including combinations thereof. Non-limiting examples of chlorine-containing compounds can include Cl_2 , SiH_2Cl_2 , HCl, SiCl_4 , and the like, including combinations thereof. Dopants can also include arsenic-containing compounds such as AsH_3 and the like, as well as antimony-containing compounds. Additionally, dopant materials can include mixtures or combinations across dopant groups, i.e. a sulfur-containing compound mixed with a chlorine-containing compound. In one aspect, the dopant material can have a density that is greater than air. In one specific aspect, the dopant material can include Se, H_2S , SF_6 , or mixtures thereof. In yet another specific aspect, the dopant can be SF_6 and can have a predetermined concentration range of about 5.0×10^{-8} mol/cm³ to about 5.0×10^{-4} mol/cm³. SF_6 gas is a good carrier for the incorporation of sulfur into the semiconductor material via a laser process without significant adverse effects on the silicon material. Additionally, it is noted that dopants can also be liquid solutions of n-type or p-type dopant materials dissolved in a solution such as water, alcohol, or an acid or basic solution. Dopants can also be solid materials applied as a powder or as a suspension dried onto the wafer.

[0092] Accordingly, the first doped region and the second doped region can be doped with an electron donating or hole donating species to cause the regions to become more positive or negative in polarity as compared to each other and/or the semiconductor device layer. In one aspect, for example, either doped region can be p-doped. In another aspect, either doped region can be n-doped. In one aspect, for example, the first doped region can be negative in polarity and the second doped region can be positive in polarity by doping with p+ and n- dopants. In some aspects, variations of n(--), n(-), n(+), n(++), p(--), p(-), p(+), or p(++ type doping of the regions can be used. Additionally, in some aspects the semiconductor material can be doped in addition to the first and second doped regions. The semiconductor material can be doped to have a doping polarity that is different from one or more of the first and second doped regions, or the semiconductor material can be doped to have a doping polarity that is the same as one or more of the first and second doped regions. In one specific aspect, the semiconductor material can be doped to be p-type and one or more of the first and second doped regions can be n-type. In another specific aspect, the semiconductor material can be doped to be n-type and one or more of the first and second doped regions can be p-type. In one aspect, at least one of the first or second doped regions has a surface area of from about $0.1 \mu\text{m}^2$ to about $32 \mu\text{m}^2$.

[0093] As has been described, the textured region can function to diffuse electromagnetic radiation, to redirect electromagnetic radiation, and to absorb electromagnetic radiation, thus increasing the QE of the device. The textured region can include surface features to increase the effective absorption length of the silicon material. The surface features can be cones, pyramids, pillars, protrusions, microlenses, quantum dots, inverted features and the like. Factors

such as manipulating the feature sizes, dimensions, material type, dopant profiles, texture location, etc. can allow the diffusing region to be tunable for a specific wavelength. In one aspect, tuning the device can allow specific wavelengths or ranges of wavelengths to be absorbed. In another aspect, tuning the device can allow specific wavelengths or ranges of wavelengths to be reduced or eliminated via filtering.

[0094] As has been described, a textured region according to aspects of the present disclosure can allow a silicon material to experience multiple passes of incident electromagnetic radiation within the device, particularly at longer wavelengths (i.e. infrared). Such internal reflection increases the effective absorption length to be greater than the thickness of the semiconductor device layer. This increase in absorption length increases the quantum efficiency of the device, leading to an improved signal to noise ratio. The textured region can be associated with the surface nearest the impinging electromagnetic radiation, or the textured region can be associated with a surface opposite in relation to impinging electromagnetic radiation, thereby allowing the radiation to pass through the silicon material before it hits the textured region. Additionally, the textured region can be doped. In one aspect, the textured region can be doped to the same or similar doping polarity as the silicon device layer so as to provide a doped contact region on the backside of the device.

[0095] The textured region can be formed by various techniques, including lasing, chemical etching (e.g. anisotropic etching, isotropic etching), nanoimprinting, additional material deposition, reactive ion etching, and the like. One effective method of producing a textured region is through laser processing. Such laser processing allows discrete locations of the semiconductor device layer to be textured. A variety of techniques of laser processing to form a textured region are contemplated, and any technique capable of forming such a region should be considered to be within the present scope. Laser treatment or processing can allow, among other things, enhanced absorption properties and thus increased electromagnetic radiation focusing and detection.

[0096] In one aspect, for example, a target region of the silicon material can be irradiated with laser radiation to form a textured region. Examples of such processing have been described in further detail in U.S. Pat. Nos. 7,057,256, 7,354,792 and 7,442,629, which are incorporated herein by reference in their entireties. Briefly, a surface of a semiconductor material such as silicon is irradiated with laser radiation to form a textured or surface modified region. Such laser processing can occur with or without a dopant material. In those aspects whereby a dopant is used, the laser can be directed through a dopant carrier and onto the silicon surface. In this way, dopant from the dopant carrier is introduced into a target region of the silicon material. Such a region incorporated into a silicon material can have various benefits in accordance with aspects of the present disclosure. For example, the target region typically has a textured surface that increases the surface area of the laser treated region and increases the probability of radiation absorption via the mechanisms described herein. In one aspect, such a target region is a substantially textured surface including micron-sized and/or nano-sized surface features that have been generated by the laser texturing. In another aspect, irradiating the surface of the silicon material includes exposing the laser radiation to a dopant such that irradiation incorporates the dopant into the semiconductor. Various

dopant materials are known in the art, and are discussed in more detail herein. It is also understood that in some aspects such laser processing can occur in an environment that does not substantially dope the silicon material (e.g. an argon atmosphere).

[0097] Thus the surface of the silicon material that forms the textured region is chemically and/or structurally altered by the laser treatment, which may, in some aspects, result in the formation of surface features appearing as nanostructures, microstructures, and/or patterned areas on the surface and, if a dopant is used, the incorporation of such dopants into the semiconductor material. In some aspects, such features can be on the order of 50 nm to 20 μ m in size and can assist in the absorption of electromagnetic radiation. In other words, the textured surface can increase the probability of incident radiation being absorbed by the silicon material.

[0098] In another aspect, at least a portion of the textured region and/or the semiconductor material can be doped with a dopant to generate a back surface field. A back surface field can function to repel generated charge carriers from the backside of the device and toward the junction to improve collection efficiency and speed. The addition of a back surface field can increase charge carrier collection and depletion. The presence of a back surface field also acts to suppress dark current contribution from the surface of a device.

[0099] While the imager device can operate in the absence of a bias at high speeds, in one aspect a reverse bias can be applied across the electrical contacts associated with the imager. Such a reverse bias can function to decrease the response time of the device by more quickly sweeping charge carriers from the silicon material. Accordingly, for those situations whereby a bias is used, any bias voltage capable of sweeping charge carriers from the silicon material is considered to be within the present scope. In one aspect, for example, the reverse bias is from about 0.001 V to about 20 V. In another aspect, the reverse bias is from about 0.001 V to about 10 V. In yet another aspect, the reverse bias is from about 0.001 V to about 5 V. In a further aspect, the reverse bias is from about 0.001 V to about 3 V. In yet a further aspect, the reverse bias is from about 3 V to about 5 V. In some aspects, the reverse bias can be absent, or in other words, 0 V is applied across the first and second contacts. In such cases, the charge carriers can be depleted from the silicon material by the junction potential created by the first and second doped regions.

[0100] In another aspect, as is shown in FIG. 4, a semiconductor device layer **402** can have a first doped region **404**, a second doped region **406**, and a textured region **408** on an opposing surface to the doped regions. An antireflective layer **410** can be coupled to the semiconductor device layer **402** on the opposite surface as the textured layer **408**. In some aspects, the antireflective layer **410** can be on the same side of the semiconductor device layer **402** as the textured region (not shown). Furthermore, in some aspects a lens can be optically coupled to the semiconductor device layer and positioned to focus incident electromagnetic radiation into the semiconductor device layer.

[0101] In another aspect of the present disclosure, a photodiode array is provided as the imager device. Such an array can include a semiconductor device layer having an incident light surface, at least two photodiodes in the semiconductor device layer, where each photodiode includes a first doped region and a second doped region forming a junction, and a

textured region coupled to the semiconductor device layer and positioned to interact with electromagnetic radiation. The textured region can be a single textured region or multiple textured regions. Additionally, the photodiode array has a response time of from about 0.1 ms to about 1 ms and an external quantum efficiency of at least 33% for electromagnetic radiation having at least one wavelength greater than about 800 nm. The photodiode array can have a pixel count, or also commonly known as the pixel resolution equal to or greater than about 320×280. In another embodiment the pixel resolution is greater than 1 MP (megapixel), greater than 5 MP, greater than 15 MP and even greater than 25 MP.

[0102] As is shown in FIG. 5, for example, a semiconductor device layer 502 can include at least two photodiodes 504 each having a first doped region 506 and a second doped region 508. A textured region 510 can be positioned to interact with electromagnetic radiation. FIG. 5 shows a separate textured region for each photodiode. In some aspects, however, a single textured region can be used to increase the absorption path lengths of multiple photodiodes in the array. Furthermore, an isolation structure 512 can be positioned between the photodiodes to electrically and/or optically isolate the photodiodes from one another. In another aspect, the photodiode array can be electronically coupled to electronic circuitry to process the signals generated by each photodiode.

[0103] Various imager configurations and components are contemplated, and any such should be considered to be within the present scope. Non-limiting examples of such components can include a carrier wafer, electrical contacts, an antireflective layer, a dielectric layer, circuitry layer, a via(s), a transfer gate, an infrared filter, a color filter array (CFA), an infrared cut filter, an isolation feature, and the like. Additionally, such devices can have light absorbing properties and elements as has been disclosed in U.S. patent application Ser. No. 12/885,158, filed on Sep. 17, 2010 which is incorporated by reference in its entirety. It is further understood that the imager can be a CMOS (Complementary Metal Oxide Semiconductor) imaging sensor or a CCD (Charge Coupled Device).

[0104] Imager device can include a number of transistors per pixel depending on the desired design of the device. In one aspect, for example, an imager device can include at least three transistors. In other aspects, an imaging device can have four, five, or six or more transistors. For example, FIG. 6 shows an exemplary schematic for a six-transistor (6-T) architecture that will allow global shutter operation according to one aspect of the present disclosure. The imager can include a photodiode (PD), a global reset (Global_RST), a global transfer gate (Global_TX), a storage node, a transfer gate (TX1), reset (RST), source follower (SF), floating diffusion (FD), row select transistor (RS), power supply (Vaapix) and voltage out (Vout). Due to the use of extra transfer gate and storage node, correlated-double-sampling (CDS) is allowed. Therefore, the read noise should be able to match typical CMOS 4T pixels.

[0105] While a rolling shutter is considered to be within the present scope, the use of a global shutter can be beneficial for use in the present devices and systems. For example, FIGS. 7a-b show images of the iris of a subject captured by an IR sensitive imager device. As can be seen in FIG. 7a, an image of an iris captured using a rolling shutter is somewhat distorted due to movements during capture. These distortions may affect identification of the

individual. FIG. 7b, on the other hand, shows an image of an iris captured using a global shutter that is a more defined and does not show such distortion. The global shutter operates by electronically activating all pixels at precisely the same time, allowing them to integrate the light from the scene at the same time and then stop the integration at the same time. This eliminates rolling shutter distortion. The global shutter image was taken under the same conditions as the rolling shutter. Thus, it would be advantages to utilize a global shutter with the photoimaging device to obtain undistorted images, particularly if the subject is in motion.

[0106] In another aspect of the present disclosure, the biometric system can include a three dimensional (3D) photosensing imager. Such a 3D-type imager can be useful to image surface details of an individual for identification, such as facial features, body features, stride or body position features, and the like. Time-of-flight (TOF) is one technique developed for use in radar and LIDAR (Light Detection and Ranging) systems to provide depth information that can be utilized for such 3D imaging. The basic principle of TOF involves sending a signal to an object and measuring a property of the returned signal from a target. The measured property is used to determine the TOF. Distance to the target is therefore derived by multiplication of half the TOF and the velocity of the signal.

[0107] FIG. 8 illustrates a TOF measurement with a target having multiple surfaces that are separated spatially. Equation (III) can be used to measure the distance to a target where d is the distance to the target and c is the speed of light.

$$d = \frac{TOF * c}{2} \quad (III)$$

[0108] By measuring the time (e.g. TOF) it takes for light emitted from a light source 802 to travel to and from a target 804, the distance between the light source (e.g. a light emitting diode (LED)) and the surface of the target can be derived. For such an imager, if each pixel can perform the above TOF measurement, a 3D image of the target can be obtained. The distance measurements become difficult with TOF methods when the target is relatively near the source due to the high speed of light. In one aspect, therefore, a TOF measurement can utilize a modulated LED light pulse and measure the phase delay between emitted light and received light. Based on the phase delay and the LED pulse width, the TOF can be derived. As such, the TOF concept can be utilized in both CMOS and CCD sensors to obtain depth information from each pixel in order to capture an image used for identification of an individual.

[0109] As one example, a 3D pixel, such as a TOF 3D pixel with enhanced infrared response can improve depth accuracy, which in turn can show facial features in a three dimensional scale. In one aspect, a photoimager array can include at least one 3D infrared detecting pixel and at least one visible light detecting pixel arranged monolithically in relation to each other. FIGS. 9a-c show non-limiting example configurations of pixel arrangements of such arrays. FIG. 9a shows one example of a pixel array arrangement having a red pixel 902, a blue pixel 904, and a green pixel 906. Additionally, two 3D TOF pixels 908 having enhanced responsivity or detectability in the IR regions of the light spectrum are included. The combination of two 3D

pixels allows for better depth perception. In FIG. 9b, the pixel arrangement shown includes an imager as described in FIG. 9a and three arrays of a red pixel, a blue pixel, and two green pixels. Essentially, one TOF pixel replaces one quadrant of a RGGB pixel design. In this configuration, the addition of several green pixels allows for the capture of more green wavelengths that is needed for green color sensitivity need for the human eye, while at the same time capturing the infrared light for depth perception. It should be noted that the present scope should not be limited by the number or arrangements of pixel arrays, and that any number and/or arrangement is included in the present scope. FIG. 9c shows another arrangement of pixels according to yet another aspect.

[0110] In some aspects, the TOF pixel can have an on-pixel optical narrow band pass filter. The narrow band pass filter design can match the modulated light source (either LED or laser) emission spectrum and may significantly reduce unwanted ambient light that can further increase the signal to noise ratio of modulated IR light. Another benefit of increased infrared QE is the possibility of high frame rate operation for high speed 3D image capture. An integrated IR cut filter can allow a high quality visible image with high fidelity color rendering. Integrating an infrared cut filter onto the sensor chip can also reduce the total system cost of a camera module (due to the removal of typical IR filter glass) and reduce module profile (good for mobile applications). This can be utilized with TOF pixels and non-TOF pixels.

[0111] FIG. 10 shows an exemplary schematic of a 3D TOF pixel according to one aspect of the present disclosure. The 3D TOF pixel can have 11 transistors for accomplishing the depth measurement of the target. In this embodiment, the 3D pixel can include a photodiode (PD), a global reset (Global_RST), a first global transfer gate (Global_TX1), a first storage node, a first transfer gate (TX1), a first reset (RST1), a first source follower (SF1), a first floating diffusion (FD1), a first row select transistor (RS1), a second global transfer gate (Global_TX2), a second storage node, a second transfer gate (TX2), a second reset (RST2), a second source follower (SF2), a second floating diffusion (FD2), a second row select transistor (RS2), power supply (Vaapix) and voltage out (Vout). Other transistors can be included in the 3D architecture and should be considered within the scope of the present invention. The specific embodiment with 11 transistors can reduce motion artifacts due to the global shutter operation, thereby giving more accurate measurements.

[0112] In another aspect, thermal imaging can be utilized for identification of an individual or a group of individuals exhibiting thermal-related characteristics. As is shown in FIG. 11 for example, such an imager can include a silicon device layer 1102 having a first doped region 1104 and a second doped region 1106 forming at least one junction. Numerous configurations are contemplated, and any type of junction configuration is considered to be within the present scope. For example, the first and second doped regions can be distinct from one another, contacting one another, overlapping one another, etc. In some cases, an intrinsic region can be located at least partially between the first and second doped regions. The device can also include a textured region 1108 coupled to the silicon device layer 1102 and positioned to interact with incoming electromagnetic radiation 1110. In this case, the textured region 1108 is located on a side of the silicon device layer 1102 that is opposite to the first doped

region 1104 and the second doped region 1106. The textured region 1108 can be associated with an entire surface of the silicon material or only a portion thereof. Further a thermal sensing layer 1112, such as a bolometer or microbolometer, can be coupled to the silicon device layer 1102. In one aspect, a cavity or void is disposed between the thermal sensing layer and the silicon material (not shown). Further details relating to such a device can be found in U.S. Pat. No. 7,847,253, which is incorporated by reference in its entirety. Such a device as shown in FIG. 11 can have the benefits of measuring facial and/or iris features as well as the thermal signature or feature of an individual.

[0113] As has been described, the system for identifying an individual can include a light source that is either a passive light source (e.g. sunlight, ambient room lighting) or an active light source (e.g. an LED or lightbulb) that is capable of emitting IR light. The system can utilize any source of light that can be beneficially used to identify an individual. As such, in one aspect the light source is an active light source. Active light sources are well known in the art that are capable of emitting light, particularly in the IR spectrum. Such active light sources can be continuous or pulsed, where the pulses can be synchronized with light capture at the imaging device. While various light wavelengths can be emitted and utilized to identify an individual, IR light in the range of from about 700 nm to about 1200 nm can be particularly useful. Additionally, in some aspects the active light source can be two or more active light sources each emitting infrared electromagnetic radiation at distinct peak emission wavelengths. While any distinct wavelength emissions within the IR range can be utilized, non-limiting examples include 850 nm, 940 nm, 1064 nm, and the like. In some aspects, the two or more active light sources can interact with the same imager device, either simultaneously or with an offset duty cycle. Such configurations can be useful for independent capture of one or more unique features of the individual for redundant identification. This redundant identification can help insure accurate authorization or identification of the individual. In other aspects, the two or more active light sources can each interact with a different imager device.

[0114] In some aspects, the system including the imager device and the light source can be in a fixed position. This may be useful in situations, for example, where the environment facilitates individuals walking directly toward the imager device. In some cases, a fixed position imager device can be associated with a zoom lens to allow zooming along a fixed viewing axis. In other aspects, it can be beneficial to allow movement of the imager device and/or the light source. Thus, a system capable of panning and/or tilting and zooming can track an individual during the identification process. It is noted that for purposes of the present disclosure, panning includes movement of a device in any direction. For example, in one aspect a system can include a pan and zoom module. Such a module allows the system to locate a feature of the individual, such as the iris, zoom in on that feature to optimize the imager device (e.g. camera) and/or light source angle to capture an electronic representation for identification purposes. Such a movement system can be manually or automatically operated.

[0115] In one specific aspect, the identification system can include at least two imager devices. The imager devices can be mounted together in a manner that allows dependent or independent movement. In one aspect, the imager devices

can be utilized to each capture an identification feature of an individual for redundant identification testing. For example, each imager can capture an independent image using the same or different light sources and compare the identification results. In other aspects, the two or more imagers can function together to capture the electronic representation of the individual. For example, in one aspect, the system can include a first imager device positioned and operable to generate a facial electronic representation of the individual and a second imager device positioned and operable to generate an iris electronic representation of the individual. In such a configuration, the system can also include an image processing circuit that finds the location of the eye from the facial electronic representation and then providing that location to circuit that controls the pan, tilt and zoom functions.

[0116] The system can also include an analysis module functionally coupled to the imager device to compare the substantially unique identification trait with a known identification trait to facilitate identification of the individual. For example, the analysis module can obtain known data regarding the identity of an individual from a source such as a database and compare this known data to the electronic representation being captured by the imager device. Various algorithms are known that can analyze the image to define the biometric boundaries/measurements and convert the biometric measurements to a unique code. The unique code can then be stored in the database to be used for comparison to make positive identification of the individual. Such an algorithm has been described for iris detection in U.S. Pat. Nos. 4,641,349 and 5,291,560, which are incorporated by reference in their entirety. It should be noted that the image processing module and the analysis module can be the same or different modules. It is understood that the system described herein can be utilized with any of the identification algorithm.

[0117] In another aspect, the system can utilize an automatic pan and zoom module to move at least one of the imager device or the light source and a process module to analyze a facial electronic representation. The process module can provide pan and zoom module coordinates for the face and iris for further zooming, movement, and image capture.

[0118] Furthermore, it is noted that in various aspects the present systems can be sized to suit a variety of applications. This is further facilitated by the potential thin film design and the increased sensitivity of the imager devices to IR light and the corresponding decrease in the intensity of IR emission, thus allowing reduction in the size of the light source. In one aspect, for example, the light source, the imager device, and the image processing module collectively have a size of less than about 160 cubic centimeters. In yet another aspect, the light source, the imager device, and the image processing module collectively have a size of less than about 16 cubic centimeters. In yet another aspect, the imager device can have an optical format of about $\frac{1}{7}$ inches.

[0119] In another aspect, the system can be activated by a trigger from the individual, whether the individual has knowledge of the trigger or not. The trigger can be a transistor or sensor integrated in the system that is capable of activating the system. Such triggers can be a thermal sensor, motion sensor, photosensor and other like sensors.

[0120] The systems according to aspects of the present disclosure can additionally be designed to be concealed from an individual being identified. It should be noted, that other

systems that incorporate imager devices having enhanced QE for electromagnetic radiation having wavelengths in the range of about 800 nm to about 1200 nm can also be concealed from an individual by a transparent IR medium as described herein. The increased responsivity or enhanced QE of the present imager devices can allow an IR light signal to be reflected off of an individual and captured behind an optically opaque but IR transparent surface, medium, or material. For example, an imager device can be located behind an IR transparent material such as glass or plastic being at least partially coated with an infrared transparent paint or other IR transparent medium substrate. In some aspects, the IR transparent medium is visually opaque. In one aspect, metal particles can be impregnated into at least a portion of the infrared transparent medium. In yet another aspect, quantum dots may be disposed on a portion of the IR transparent medium such that the IR light is transmitted through the medium while other light is filtered out. The IR transparent material can be any material that allows the transmission of IR light. The IR light source can be directed toward the individual to be identified from either side of the IR transparent material. Reflections of the IR light source are then captured by the imager device for identity processing. It is noted that the concealment of an IR imager in such a manner can be utilized in association with any method or technique using an IR imaging system, and should not be limited to identification of an individual. It is also noted that, in addition to locating the imager behind an IR transparent material, concealment can also be accomplished through the obscured placement of an IR imager having a small footprint. Given the small footprint and the desired electronic devices, the system disclosed herein can consume small amount of power from the electronic device. In one aspect, the system can use less than 5 watts, less than 3 watts and even less than 1 watt of power.

[0121] In other aspects, the identification system can be integrated into an electronic device. Non-limiting examples of such devices can include mobile smart phones, cellular phones, laptop computers, desktop computers, tablet computers, ATMs, and the like. In one specific aspect, positive identification of the individual is operable to unlock the electronic device. In this example, the electronic device stores an encrypted authorized user's facial and iris identification trait in a storage registry and an individual's identification traits are captured by an authorization system incorporated into the electronic device. The authorization system can compare the individual's identification trait with the stored authorized user's identification trait for positive identification. This aspect is beneficial for verifying an individual in a financial or legal transaction or any other transaction that requires identification and/or signature. It is contemplated herein, that ATM financial transactions may include a user authorization system where the encrypted authorized user's identification trait is stored on an ATM debit card, such that the ATM device can compare the individual's identification trait with the authorized user trait stored on the card for a positive identification. A similar system can be utilized for credit cards or any other item of commerce.

[0122] In another example, a financial transaction may be accomplished via a cell phone device where the authorization system is continuously verifying the authorized user during the duration of the financial transaction via a front side or cameo imaging devices incorporated into the cell

phone. Furthermore, in a cell phone embodiment, the imager device can include a switch such that the user can toggle between infrared light capture and visible light capture modes.

[0123] In FIG. 12, an electronic device can include an integrated user authorization system **1200** that can be configured to continuously verify and authorize a user. Such a system can include an imager device **1202** including a semiconductor device layer having a thickness of less than about 10 microns, at least two doped regions forming a junction, and a textured region positioned to interact with the electromagnetic radiation, wherein the imaging device has an external quantum efficiency of at least about 33% for electromagnetic radiation having at least one wavelength of greater than 800 nm, where the imager device is positioned to capture an electronic representation of an identification trait of a user of the device. The imager device at least periodically captures an electronic representation of the user. The system can also include a storage register **1206** operable to store a known identification trait of an authorized user and an analysis module **1208** electrically coupled to the imager device and the storage register, where the analysis module is operable to use algorithms to generate an electronic representation and compare the electronic representation of the identification trait to the known identification trait to verify that the user is the authorized user. Thus an authorized user can continuously use the device while an unauthorized user will be precluded from doing so. In one aspect, the system can include a light source operable to emit electromagnetic radiation having at least one wavelength of from about 700 nm to about 1200 nm toward the user.

[0124] In another aspect, a second imager device **1204** can be incorporated into the system. The second imager device can be an IR enhanced imaging device configured to detect electromagnetic radiation having a wavelength in the range of about 800 nm to about 1200 nm. The second imager device can be configured to exclusively track an individual iris, face or both. In another aspect the second imager device can be configured to detect visible light and can be a cameo type imager. In another embodiment, a trigger **1210** (e.g. motion sensor) and a switch **1212** can optionally be incorporated in the user authorization system allowing the system to be activated and toggled between a first imager device and a second imager device. Furthermore, a first or second imager device can include a lens or optic element for assisting in the capturing the electronic representation of an individual.

[0125] Given the continuous nature of the user authorization system, it can be beneficial to separate the authorization system from the processing system of the electronic device in order to decrease CPU load. One technique for doing so includes monolithically integrating the analysis module and the imager device together on the same semiconductor device layer and separate from the CPU of the electronic device. In this way the authorization system functions independently from the CPU of the electronic device.

[0126] Furthermore, in some aspects the authorization system can include a toggle to switch the imager device between IR light capture and visible light capture. As such, the imager can switch between authorizing the user and capturing visible light images.

[0127] Furthermore, it can be beneficial to encrypt the known identification trait for security reasons. Such encryp-

tion can protect an authorized user from identity theft or unauthorized use of an electronic device.

[0128] In another aspect of the present disclosure, a method of identifying an individual is provided. As is shown in FIG. 13, such a method can include emitting infrared electromagnetic radiation having at least one wavelength of from about 700 nm to about 1200 nm toward the individual **1302**, receiving the infrared electromagnetic radiation reflected from the individual into an imager device to generate an electronic representation of the individual **1304**, processing the electronic representation into an individual representation having at least one substantially unique identification trait **1306**, and using the at least one substantially unique identification trait to identify the individual **1308**. The imager device includes a semiconductor device layer, at least two doped regions forming a junction, and a textured region positioned to interact with the electromagnetic radiation, wherein the imaging device has an external quantum efficiency of at least about 30% for electromagnetic radiation having at least one wavelength of greater than 800 nm.

[0129] A variety of identification traits can be utilized to identify an individual, and any identification trait capable of being utilized for such identification is considered to be within the present scope. Non-limiting examples of such identification traits include facial features, iris patterns, body posture, gait, thermal images, and the like. In one specific aspect, the substantially unique identification trait can include an electronic representation of an iris sufficient to identify the individual. As has been described, the enhanced responsivity of the present system can facilitate the capture of an electronic representation of the iris across a wide range of distances. In one aspect, for example, the electronic representation of the iris can be captured by the imager device at a distance of from about 0.5 m to about 15 m from the individual. In another aspect, the electronic representation of the iris can be captured by the imager device at a distance of from about 2 m to about 10 m from the individual. In a further aspect, the electronic representation of the iris can be captured at a distance of greater than 2 m from the imager device to the individual using the infrared electromagnetic radiation at an intensity that is below 10,000 mW/mm²/steradians.

[0130] Of course, it is to be understood that the above-described arrangements are only illustrative of the application of the principles of the present disclosure. Numerous modifications and alternative arrangements may be devised by those skilled in the art without departing from the spirit and scope of the present disclosure and the appended claims are intended to cover such modifications and arrangements. Thus, while the present disclosure has been described above with particularity and detail in connection with what is presently deemed to be the most practical embodiments of the disclosure, it will be apparent to those of ordinary skill in the art that numerous modifications, including, but not limited to, variations in size, materials, shape, form, function and manner of operation, assembly and use may be made without departing from the principles and concepts set forth herein.

1. A system for identifying an individual, comprising:
 - an active light source capable of emitting electromagnetic radiation having at least one wavelength of from about 700 nm to about 1200 nm;
 - an imager device positioned to receive the electromagnetic radiation upon reflection from an individual to

- generate an electronic representation of the individual, the imager device including a semiconductor device layer having a thickness of less than about 10 microns, at least two doped regions forming a junction, and a textured region positioned to interact with the electromagnetic radiation, wherein the imaging device has an external quantum efficiency of at least about 33% for electromagnetic radiation having at least one wavelength of greater than 800 nm; and
- an image processing module functionally coupled to the imager device and operable to receive the electronic representation, wherein the image processing module is operable to process the electronic representation into an individual representation having at least one substantially unique identification trait.
2. The system of claim 1, wherein the semiconductor device layer is coupled to a bulk semiconductor.
3. The system of claim 1, wherein the active light source is two or more active light sources each emitting infrared electromagnetic radiation at distinct peak emission wavelengths.
4. The system of claim 3, wherein the two or more active light sources emit infrared electromagnetic radiation at about 850 nm and about 940 nm.
5. The system of claim 1, wherein the imager device is capable of capturing the electronic representation with sufficient detail to identify the at least one substantially unique identification trait using electromagnetic radiation emitted from the active light source having at least one wavelength of from about 700 nm to about 1200 nm and having a scene radiance impinging on the individual at 3 meters that is at least 0.1 mW/mm².
6. The system of claim 1, wherein the imager device is silicon-based and has a response time of from about 0.1 ms to about 1 ms and an external quantum efficiency of at least about 33% for electromagnetic radiation having at least one wavelength of greater than 800 nm.
7. The system of claim 1, wherein the imager device is silicon-based and has a response time of from about 0.1 ms to about 1 ms and an external quantum efficiency of at least about 11% for electromagnetic radiation having at least one wavelength of greater than 940 nm.

8. The system of claim 1, further comprising an analysis module functionally coupled to the image processing module, wherein the analysis module is operable to compare the at least one substantially unique identification trait with a known identification trait to facilitate identification of the individual.

9. The system of claim 1, further comprising an automatic pan and zoom module operable to move at least one of the light source or the imager device in order to track the individual.

10. The system of claim 1, wherein the imager device includes at least two imager devices.

11. The system of claim 10, wherein the at least two imager devices includes a first imager device positioned and operable to generate a facial electronic representation of the individual and a second imager device positioned and operable to generate an iris electronic representation of the individual.

12. The system of claim 11, further comprising:
an automatic pan and zoom module operable to move at least one of the active light source or the imager device;
and
a process module to analyze the facial electronic representation and provide the pan and zoom module coordinates for the face and iris.

13. The system of claim 12, wherein the system is concealed behind an infrared transparent and optically opaque medium from the individual.

14. The system of claim 1, wherein the light source, the imager device, and the image processing module collectively has a size of less than about 160 cubic centimeters.

15. The system of claim 1, further comprising an electronic device into which the system is integrated, wherein the electronic device includes at least one of a mobile smart phone, a cellular phone, a laptop computer, and a tablet computer.

16. The system of claim 15, wherein positive identification of the individual is operable to verify the individual in a financial transaction.

17-26. (canceled)
