(57) **ABSTRACT**

In a digital signal processing system, a method for selecting a transform function to apply to an input signal based on characteristics of the signal, and for self-adjusting criteria which are used in selecting a transform function to apply to a subsequent signal. Characteristics are obtained from the signal. The characteristics are compared to adjustable criteria which are used in selecting a transform function. Differing criteria are maintained for the different selectable transform functions. A record is maintained of transform functions selected and the particular characteristics that caused the selection. Based on the ability of a transform function to minimally define the coded signal, an inverse transform function is selected to decode the signal. The criteria used in selecting a transform function to apply to a subsequent signal are adjusted based on a quality measure of the decoded signal and the record of selected transform functions.

This is a continuation of U.S. patent application Ser. No. 09/396,084, filed on Sep. 14, 1999, now U.S. Pat. No. 6,229,917, which is in turn a continuation of U.S. patent application Ser. No. 08/678,427, filed on Jul. 3, 1996, now U.S. Pat. No. 6,011,864.

**BACKGROUND OF THE INVENTION**

**1. Field of the Invention**

The present invention generally relates to coding digital video images, and more particularly to reducing loss of image information by automatically adjusting operating parameters utilized in the coding process.

**2. Description of Background Art**

Digital video systems are becoming increasingly popular, especially in business settings. An example application of a digital video system is a teleconferencing system. Despite their popularity, digital video systems can be extremely expensive in terms of storage and communication costs. The cost of storage and communication is driven by the massive quantity of digital image data which is generated by the system.

One way to reduce costs or improve performance is to reduce the quantity of digital data used to represent images. Various well known compression techniques have been utilized to reduce the quantity of data used to represent a digitized image. While image compression may reduce some of the costs associated with handling digital image data, the downside is that image quality may suffer.

A number of compression techniques conventionally involve linear transformation of the digital image, followed by quantization, and coding of transform coefficients. In this way, the quantized and coded signals may be compressed, transmitted, or stored, and subsequently decompressed using an inverse set of operations.

The Discrete Cosine Transform (DCT) has commonly been used for image compression and decompression. However, because such DCT-based image processing is computationally intensive, various methods have been devised to improve the performance of the transform process.

The DCT process involves computing a set of coefficients to represent the digital image. One approach used to reduce the time required to perform the transform process is to compute only a subset of the coefficients. The selection of the particular subset of coefficients to be computed is based on detected characteristics of the digital image. While yielding acceptable results, the prior art process of classifying a digital image according to its characteristics and then selecting a subset of coefficients has no mechanism to measure the quality of the transformed image. Furthermore, the selection criteria used to classify an image are fixed such that they cannot be easily adjusted to improve image quality.

Therefore, to improve the quality of compressed digital images what is needed is a coding system having self-adjusting selection criteria for selecting a transform function.

**SUMMARY OF THE INVENTION**

The invention monitors the quality of coded digital images, and based on the monitored quality of the images, updates operating parameters that are used in coding the images.

A set of predetermined coding functions is available in a video coding system to code a digitized video image. One of the coding functions is selected and applied to the input image. The selection of the coding function is made based upon measured characteristics of the input image and selection criteria which are applied to the measured characteristics. The image is then decoded and the quality of the decoded image is measured. The selection criteria are updated based on the measured quality of the decoded image, whereby for subsequent images coding functions are selected to produce images with a higher quality measure.

In another aspect of the invention, an historical record is made for the measured characteristics of the images processed by the system. The measured characteristics are correlated with the selected coding function. Periodically, the selection criteria are updated based on the historical record. The historical record provides a broad perspective upon which updating of the selection criteria is based.

The invention further selects one of a predetermined set of transform functions to code an image. An inverse transform function is selected, independent of the selection of the first transform function, whose application minimally covers the coefficients produced by application of the first transform function. The inverse transform function is then applied to the coefficients, the quality is measured, and the selection criteria are updated as described above. The updating of the selection criteria enables selection of a suitable transform function.

In still another aspect of the invention, the selection criteria include adjustable thresholds and comparisons of them to measured characteristics of the image to be coded. The measured characteristics are correlated to the selected inverse transform function in the historical record. The respective thresholds are then updated from the historical record of the measured characteristics.

**BRIEF DESCRIPTION OF THE DRAWINGS**

FIG. 1 is a block diagram of a computer system for encoding video sequences;

FIG. 2 is a block diagram of a prior art video coding system;

FIG. 3 is a block diagram of a video coding system which utilizes the present invention;

FIG. 4 shows the relationship between FIGS. 4A and 4B which together contain a flowchart of the processing performed by the video coding system in utilizing the present invention;

FIG. 5 shows the Total Energy Threshold Array memory map;

FIG. 6 shows the memory map of a block which is output after the application of the Four-by-Four block transform function;

FIG. 7 illustrates the memory map of the Decoded Block Quality Array; and

FIG. 8 illustrates the memory map of the Total Energy histogram.

**DETAILED DESCRIPTION**

FIG. 1 is a block diagram of a computer system **100** for encoding video sequences. The exemplary system **100** is a Power Macintosh which is available from Apple Computer, Inc. The system includes a central processing unit (CPU) **102**, an input device **104** such as a keyboard or a mouse, and an output device **106** such as a computer monitor. The

system **100** further includes data storage **108** which may consist of magnetic disks and/or tapes, optical storage, or various electronic storage media. The RAM **110** is available for storage of program instructions and data as referenced by the CPU **102**. The functional units of the system **100** are interconnected by a signal bus **112**.

An operating system program **114** is shown as stored in the RAM **110** to indicate that the program is executable by the CPU **102**, even though only portions of the program may be present in the RAM at a given time. The operating system **114** controls allocation of the resources which are available in the system **100**.

The system **100** further includes a video input device **116** which is coupled to the bus **112**. The video input device **116** captures and digitizes frames of images presented to a camera portion of the video input device **116**. The video coding system program **118**, represented as being stored in the RAM **110**, compresses the frames of data input by the video input device **116**. The compressed frames may then, depending upon the application, be either stored on the data storage **108** as video frames **120**, or output to a receiving application via the network input/output device **122**.

FIG. 2 is a block diagram of a prior art video coding system **150**. The video coding system **150** has program modules comprising a color converter **152**, a motion estimator **154**, a transform processor **156**, a classifier **158**, a quantization processor **160**, a lossless coder **162**, an inverse quantization processor **164**, an inverse transform processor **166**, and a motion compensator **168**, the latter three of which provide feedback data to the motion Estimator **154**.

The color converter **152** receives a frame of a digitized video image via input line **170** and converts the frame from Red-Green-Blue (RGB) format to a luminance-chrominance format such as Yuv. The converted frame is provided as input to a summation element **172**. The second input to the summation element **172** is provided by the motion estimator **154**.

The motion estimator **154** receives as input a frame from color converter **152** as shown by line **174**. The previously processed frame is also input to the motion estimator **154** as shown by line **176**. The motion estimator **154** compares the frames to estimate the movement of portions of the image in the frame. The output of the motion estimator **154** is provided to the summation element **172** which outputs a residual frame on line **178** to the transform processor **156**. The residual frame is essentially the difference between the present frame as input on line **174** and the previous frame as input on line **176**.

The transform processor **156** receives the residual frame from the summation element **172**. The input frame is processed one block at a time, where a block is an  $m \times n$  array of elements of the input frame. Each element of the block represents a pixel of data. In the exemplary embodiment the block size is an  $8 \times 8$  array of pixel data. The input frame is also input to the classifier **158** via line **178**.

The transform processor **156** applies a Discrete Cosine Transform function to the input block to obtain an output block of coefficients. Background material on transform coding of images may be found in *Transform Coding of Images*, R. J. Clarke, Academic Press (London), 1985. To save computation time, the transform processor **156**, based on a selection made by the classifier **158**, may compute only a subset of the coefficients of the block. The classifier **158** determines characteristics of the input block, and based on predetermined selection criteria, selects for computation a subset of the coefficients of the block. Note, however, that a

block having certain characteristics will result in the computation of all coefficients of a block. The selected subset of coefficients to compute is input to the transform processor **156** as shown by line **182**. The selected subset of coefficients which is selected for computation is hereinafter referred to as the "transform function" or "transform type."

Each block of coefficients output by the transform processor **156** is input on line **184** to the quantization processor **160**. The quantization processor **160** reduces the number of bits required to represent each of the coefficients in the block by dividing each coefficient by a predetermined constant. The predetermined constant is selected based on the application's required bit transmission rate.

The block of quantized coefficients is input on line **186** to the lossless coder **162**. The lossless coder **162** codes the block and outputs the coded information on line **188** for storage to data storage **108**, output on network input/output **122**, or output to output device **106**.

The block of quantized coefficients is also provided as feedback on line **190** to the inverse quantization processor **164**, to the inverse transform processor **166**, and to the motion compensator **168**. The purpose of the feedback data is to permit the motion estimator **154** to perform its estimation by comparing a newly input frame to a frame of the previous image as viewed by an application receiving the output of lossless coder **162**.

The inverse quantizer **164** multiplies each coefficient of the input quantized block by the same predetermined constant that was used by the quantization processor **160**. The output of the inverse quantizer **164** is provided via line **192** as input to the inverse transform processor **166**.

The inverse transform processor **166** performs the inverse of the transform function performed by the transform processor **156** and as indicated by the classifier **158** on line **194**. The motion compensator **168** obtains the block of pixels from the previously decoded image which is offset by the motion vectors from the block of interest. The summation element **196** performs a pixel-wise addition of the negated output of the motion compensator **168** with the incoming block.

FIG. 3 is a block diagram of a video coding system **300** which utilizes the present invention. The elements added to FIG. 2 in FIG. 3 include a forward classifier **302**, a classifier feedback processor **304**, a quality measurement processor **306**, and an inverse classifier **308**.

The forward classifier **302** selects a transform type, which is indicative of a selectable transform function, based on the characteristics of the block input on line **180** and adjustable selection criteria as provided by the classifier feedback processor **304** on line **310**. Recall from FIG. 2 that the selectable transform function is an indication of the subset of coefficients to compute for the input block. The transform type is input on line **312** to the transform processor **156**.

The classifier feedback processor **304** provides selection criteria on line **310** to the forward classifier **302**. The selection criteria are adjusted by the classifier feedback processor **304** based on various input data, including: (1) from the forward classifier **302**, the transform type and characteristic values computed for a block as shown by line **314**; (2) from the quantization processor **160**, the quantization value,  $Q$ , on line **316**; (3) from the motion estimator **154**, motion vectors on line **318**; (4) from the quality measurement processor **306**, a Peak Signal to Noise Ratio (PSNR) on line **320**; and (5) from the inverse classifier, an inverse transform type on line **322**. The processing performed by the classifier feedback processor is explained further in the discussion pertaining to the FIGs. that follow.

Generally, the quality measurement processor **306** measures the quality of the coded images produced by the video coding system **118** for the purpose of improving the quality of subsequent images coded by the system **118**. The quality measurement processor **306** does so by indicating to the classifier feedback processor **304** the PSNR of a block which has been coded and then decoded, relative to the block input for coding. The processing performed by the quality measurement processor **306** is explained further in the discussion pertaining to the FIGs. that follow.

The inverse classifier **308** selects an inverse transform function for input on line **322** to the classifier feedback processor **304** and for input on line **324** to the inverse transform processor **166**. The inverse classifier **308** selects an inverse transform type independent of the classification performed by the forward classifier **302**. The purpose of the independent selection is decode the block so that the selection criteria used by the forward classifier **302** may be adjusted to improve the speed of the transform processor **156** while maintaining the fidelity of the coefficients which are output by the transform processor. The processing performed by the inverse classifier **308** is explained further in the discussion pertaining to the FIGs. that follow.

FIG. **4** shows the relationship between FIGS. **4A** and **4B** which together form a flowchart of the processing performed by the video coding system **300** in utilizing the present invention.

In step **402**, the video coding system **300** performs initialization by associating predetermined transform functions with image characteristics and selection criteria. FIG. **5** illustrates how the associations are established in the exemplary system. Briefly, the types of image characteristics and selection criteria utilized include adjustable thresholds of overall energy, horizontal high pass energy, vertical high pass energy, and motion vector magnitudes. The adjustable thresholds and usage thereof are explained in more detail below.

Step **404** receives an input block whose motion vector has been estimated by the Motion Estimator **154**; A motion vector consists of an x value and a y value, where x is the movement of the image in the block on an x-axis and y is the movement of the image in the block on a y-axis. The input block is received by the transform processor **156** and the forward classifier **302**, and the motion vector is received by the classifier feedback processor **304**.

The pseudocode in Table 1 below corresponds to steps **406** and **408**.

TABLE 1

```

001 ForwardClassification( Q, InputBlock, MotionVectors)
002 begin
003

029 // select the most general transform type.
15 030 return DefaultTransformType;
031
032 end

```

At step **406**, characteristic values are computed for the input block. Lines **5–8** of the pseudocode compute the respective values according to formulae set forth below:

The total energy is the image energy and is computed as the sum of the absolute pixel values. Specifically, where i and j form an index into the input block, x:

$$total\ energy = \sum_{(i,j) \in block} |x(i, j)|$$

The horizontal high pass energy is computed as the sum of absolute differences of horizontally adjacent pixel values. Specifically:

$$hHPenergy = \sum_{0 \leq i < Blockwidth-1, 0 \leq j < Blockheight} |x(i, j) - x(i+1, j)|$$

The vertical high pass energy is computed as the sum of the absolute differences of vertically adjacent pixel values. Specifically:

$$vHPenergy = \sum_{0 \leq i < Blockwidth, 0 \leq j < Blockheight-1} |x(i, j) - x(i, j+1)|$$

The motion vector magnitude may be computed as either the sum of the squares of each component, or as the maximum of the two vector components. In the exemplary embodiment either calculation is suitable. Specifically:

$$mvMag = x^2 + y^2 \text{ or} \\ mvMag = \max(x, y)$$

Lines **10–30** of the pseudocode of Table 1 correspond to step **408**. Step **408** selects a transform function based on the selection criteria set specified in lines **19–25**.

FIG. **5** shows the TotalEnergyThresholdArray memory map **452**. The memory maps for the HorizHighPassEnergyThresholdArray, the VertHighPassEnergyThresholdArray, and the MotionVectorMagnitudeThresholds are similar in character to the TotalEnergyThresholdArray of FIG. **5**. Therefore, for brevity only the EnergyThresholdArray is illustrated.

Each of the arrays has t rows, each representing a different transform function, and columns 1-MAX\_Q which represent the constants used by the quantization processor **160**. MAX\_Q is a predetermined constant. Each entry in the respective arrays is initially zero, and, during the course of processing is updated by the classifier feedback processor **304**.

The transform functions utilized in the exemplary system include Zero-block, One-by-Three, One-by-Eight, Two-by-Eight, Four-by-Four, Four-by-Eight, and Eight-by-Eight.

FIG. 6 shows the memory map of a block which is output after the application of the Four-by-Four block transform function. The transform processor 156 computes the coefficients for the upper-left four rows and four columns of the block. The computed coefficients are designated as  $C_{ij}$  in the array. The remaining entries in the array are set to zero.

The Zero-block transform function results in the transform processor 156 setting every entry in the output block to zero. The One-by-Three transform function results in the transform processor 156 computing the coefficients for the first three columns of row one of the input block, and setting the remaining entries to zero. The One-by-Eight transform function results in the transform processor 156 computing the coefficients for all eight columns of row one of the input block, and setting the remaining coefficients to zero. The Two-by-Eight transform function results in the transform processor 156 computing the coefficients for all eight columns of rows one and two, and setting the remaining coefficients to zero. The Four-by-Eight transform function results in the transform processor 156 computing the coefficients for all eight columns of the first four rows of the input block, and setting the remaining entries to zero. The Eight-by-Eight transform function results in the transform processor 156 computing the coefficients for all eight rows and eight columns of the input block. Note that the Eight-by-Eight transform function is the DefaultTransformType as returned by the ForwardClassification pseudocode of Table 1.

Returning now to FIG. 4A, the transform processor 156 performs step 410 in applying to the input block the transform function selected by the forward classifier 302. The quantization processor 160 performs step 412 in quantizing the block received from the transform processor 156. Control is directed via path 412p to steps 414 and 416 of FIG. 4B. At step 414, the lossless coder 162 codes the block and outputs the block to data storage 108 or network input/output 122.

Step 416 is performed by the inverse classifier 308. The pseudocode in Table 2 below sets forth the processing for selecting a transform function that minimally covers the coefficients of the input quantized block.

TABLE 2

```

001 InverseClassification( QuantizedCoefficientBlock )
002 begin
003
004 // Determine the locations of the non-zero coefficients.
005 locOfNonZeroCoef
006     = DetermineLocationOfForNonZeroCoefs(QuantizedCo-
007       efficientBlock );
008 // Find the transform whose set of coefficients minimally cover the
009 // non-zero
010 // coefficients
011 transformType = FindMinimalCoveringTransform( locOfNon-
012   ZeroCoef );
013
014 return transformType;
015 end

```

At lines 5–6 of the InverseClassification pseudocode, the locations of the non-zero entries in the quantized block are identified. Line 10 identifies the inverse transform function (e.g., Zero-block, One-by-Three, One-by-Eight, Two-by-Eight, Four-by-Four, Four-by-Eight, or Eight-by-Eight) whose application results in computing all coefficients for the input quantized block and which defines the smallest portion of the 8x8 block.

The inverse quantization processor 164 inversely quantizes the quantized block at step 418. Processing continues

at step 420 where the inverse transform processor 166 applies the inverse of the transform function selected by the inverse classifier 308. The decoding process continues at step 422 where the motion compensator 168 undoes the motion estimation applied by the motion estimator 154.

The quality measurement processor 306 measures the quality of the decoded block at step 424. The exemplary system uses the following calculation to measure decoded block quality (Note that  $x$  is the original input block and  $x'$  is the decoded block while each element of blocks  $x$  and  $x'$  are represented by  $x(ij)$  and  $x'(ij)$ , respectively):

$$PSNR=10\log\frac{\sum_{(i,j)\in block}(x'(i,j))^2}{$$

$$*blocksize* 255^2}$$

The quality measurement processor 306 keeps a historical record of decoded block quality values and outputs the decoded block quality on line 320 to the classifier feedback processor 304.

FIG. 7 illustrates the memory map of the Decoded Block Quality Array 462 in which historical records of decoded block quality values are kept. For each transform function/quantizer value pair, a historical record is kept of the decoded block quality values. The decoded block quality value may be the average of the PSNR values, the median of the PSNR values, the minimum of the PSNR values, or another suitable statistical measure of the PSNR values. The particular statistical function chosen is driven by application requirements.

Returning to FIG. 4B, steps 426 and 428 are performed by the classifier feedback processor 304. The classifier feedback processor 304 maintains a historical record of characteristic values and quality measures of decoded blocks, as related to the applied inverse transform function applied by the inverse transform processor 166. At step 426 the historical record is updated. The pseudocode in Table 3 below sets forth the processing for updating the historical record.

TABLE 3

```

001 procedure UpdateHistograms
002 (
003   InputBlkCharHist [NumberOfInputBlkCharTypes] [NumberOf-
004     TransformTypes] [MAX_Q],
005   InputBlkCharType,
006   InverseTransformType,
007   Q,
008   ForwardTransformType,
009   InputBlkCharValue, // Comes from the forward classifier.
010 )
011 begin
012 // The array 'NumberOfComputedCoefficients' is a constant
013 // global array.
014 NumCoefInverse = NumberOfComputedCoefficients[Inverse-
015   TransformType];
016 NumCoefForward = NumberOfComputedCoefficients[Forward-
017   TransformType];
018
019 if NumCoefInverse > SomeNiceConstant * NumCoefForward
020
021 // Select the histogram to update.
022 theHistogram = InputBlkCharHist[InputBlkCharType]
023 [InverseTransformType] [Q]
024
025 // Update the histogram.
026 theHistogram [InputBlkCharValue]++;
027 end

```

Inputs to the procedure, UpdateHistograms, include: (1) a histogram designated as InputBlkCharHist [NumberOfInput

CharTypes][NumberOfTransformTypes][MAX\_Q]; (2) a characteristic designated as InputBlkCharType; (3) the inverse transform function designated as InverseTransformType; (4) the quantization value Q; (5) the forward transform function designated as ForwardTranformType; and (6) an input characteristic value designated as InputBlkCharValue.

FIG. 8 illustrates the memory map of the Total Energy Histogram 472. The memory maps of the Horizontal High Pass Energy Histogram, the Vertical High Pass Energy Histogram, the Motion Vector Magnitude Histogram are similar in character to the Total Energy Histogram. Therefore, for brevity only the Total Energy Histogram is illustrated. Each of the histograms is singly input to the UpdateHistograms procedure of Table 3 as shown by line 3 of the pseudocode.

Each of the histograms has a row for each of the available transform functions, and a column for each value in the range of quantization values. Each entry in the array references a one-dimensional array having indices ranging from 0 to a predetermined maximum value. Values in the one-dimensional array are updated as defined by the UpdateHistograms pseudocode of Table 3. The InputBlkCharType which is input to the UpdateHistograms pseudocode specifies which histogram to update.

Returning now to FIG. 4B, at step 428 the classifier Feedback processor 304 periodically adjusts the selection criteria used by the forward classifier 302 and then returns control, via control path 428p, to step 402 to process the next block. In the exemplary embodiment, the selection criteria are adjusted once per second.

The procedure UpdateThresholds, as set forth in the pseudocode of Table 4 below, updates the selection criteria by selectively updating the various thresholds in the TotalEnergyThresholdArray (FIG. 5), the HorizHighPassEnergy Array, the VertHighPassEnergyArray, and the MotionVectorMagnitudeArray.

The inputs to the procedure are listed in lines 4–6. The input parameter at line 4 references the threshold arrays (See FIG. 5); the input at line 5 references the corresponding histograms (See FIG. 8); and the input at line 6 references the Decoded Block Quality Array (See FIG. 7).

As set forth in lines 12–40, each of the threshold arrays is updated by first selecting an order statistic to apply to the respective histogram, and then applying the selected order statistic to the respective histogram. The OrderStatistic function which is initiated on lines 31–36 applies the order-StatisticType to the referenced histogram of characteristic values. The orderStatisticType is a percentage, and the OrderStatistic function computes the characteristic value. To compute the characteristic value, the number of occurrences for all the characteristic values are totaled, and the total is multiplied by the orderStatisticType to obtain an adjusted occurrence total. Then, beginning at the lowest characteristic value in the histogram and proceeding with the following characteristic values, the number of occurrences are totaled until the adjusted occurrence total is reached. The Order-Statistic function then returns the characteristic value at which the adjusted occurrence total was reached.

The pseudocode for the function SelectOrderStatistic is set forth in Table 5 below.

The inputs to the SelectOrderStatistic function are set forth in lines 3–6. The inputs are the transform type, the quantization value, a characteristic type, and a value that indicates the quality of the decoded block.

The function SelectOrderStatistic returns an OrderStatisticType based upon the input characteristic type, a predetermined constant, the number of coefficients computed for the input transform type, and the input quality value.

While the foregoing exemplary embodiment of the invention is described in terms of a software implementation, those skilled in the art will recognize that the invention could also be implemented using logic circuits. The exemplary embodiments described herein are for purposes of illustration and are not intended to be limiting. Therefore, those skilled in the art will recognize that other embodiments could be practiced without departing from the scope and spirit of the claims set forth below.

What is claimed is:

**1.** A computer-implemented method for coding a block of pixels of a digitized video image using a selectable one of a plurality of coding functions, the method comprising:

- establishing adjustable selection criteria for selecting a coding function;
- measuring a predetermined characteristic of the block to obtain a characteristic value;
- selecting a coding function based on said adjustable selection criteria and said characteristic value;
- coding the block according to said coding function to obtain a coded block;
- performing a quality measurement of said coded block;
- adjusting said adjustable selection criteria for selecting a coding function, utilizing said quality measurement such that quality measurements of subsequent blocks are improved; and
- establishing historical records of quality values and characteristic values and associated coding functions and quantization values.

**2.** The method of claim 1, wherein said performing further comprises:

- decoding said coded block to obtain a decoded block.

**3.** The method of claim 2, further comprising selecting a decoding function independent of selecting said coding function.

**4.** The method of claim 3, further comprising:

- further establishing said historical records based on detected characteristics of blocks and selected decoding functions; and
- adjusting said adjustable selection criteria based on said historical records.

**5.** The method of claim 1, wherein said measuring measures a predetermined plurality of characteristics, and said selecting selects a coding function based on said adjustable selection criteria and said plurality of characteristics.

**6.** The method of claim 5, wherein said plurality of characteristics include a total energy characteristic defined as  $\sum_{(i,j) \in \text{block}} |x(i,j)|$ , wherein x represents the block of pixels, and i and j are indices into the block.

**7.** The method of claim 5, wherein said plurality of characteristics include a horizontal high pass energy characteristic defined as

$$\sum_{0 \leq i < \text{Blockwidth}-1, 0 \leq j < \text{BlockHeight}} |x(i,j) - x(i+1,j)|$$

wherein x represents the block of pixels, and i and j form indices into the block.

**8.** The method of claim 5, wherein said plurality of characteristics include a vertical high pass energy characteristic defined as

$$\sum_{0 \leq i < \text{Blockwidth}, 0 \leq j < \text{BlockHeight}-1} |x(i,j) - x(i,j+1)|$$

wherein x represents the block of pixels, and i and j form indices into the block.

**9.** The method of claim 5, wherein said plurality of characteristics include a motion vector magnitude characteristic, defined as  $x^2 + y^2$ , wherein x represents the movement of the image in the block on an x-axis and y represents movement of the image in the block on a y-axis.

**10.** The method of claim 5, wherein said plurality of characteristics include a motion vector magnitude characteristic defined as the maximum of x and y, wherein x represents the movement of the image in the block on an x-axis and y represents movement of the image in the block on a y-axis.

**11.** The method of claim 1, wherein said performing a quality measurement includes the obtaining a peak-signal-to-noise ratio.

**12.** The method of claim 11, further comprising:

- further establishing said historical records based on detected characteristics of blocks and selected decoding functions; and
- adjusting said adjustable selection criteria based on said historical records.

**13.** A computer-implemented method for transforming a block of pixels within a frame of a digitized video image using a selectable one of a set of transform functions, each transform function having an inverse transform function, and each block having a predetermined set of image characteristics, the method comprising:

- establishing adjustable selection criteria for selecting a transform function;
- detecting respective characteristic values for the image characteristics of a block;
- selecting a first transform function from said set of transform functions based on said characteristic values and said adjustable selection criteria;
- applying said first transform function to said block to form a transformed block;
- quantizing said transformed block to form a quantized block;
- selecting an inverse transform function whose application minimally covers said quantized block;
- inversely quantizing said quantized block to form an inversely quantized block;
- applying said inverse transform function to said inversely quantized block to form a decoded block;
- establishing a quality value for said decoded block for improving subsequent coded images;
- updating said adjustable selection criteria based on said quality value and said characteristic values; and
- establishing historical records of quality values and characteristic values and associated transform functions and quantization values.

## 13

14. A computer-implemented method for transforming a block of pixels within a frame of a digitized video image using a selectable one of a set of transform functions, each transform function having an inverse transform function, and each block having a predetermined set of image characteristics, the method comprising:

associating the transform functions with the set of image characteristics, with predetermined quantization values, and with adjustable thresholds associated with the image characteristics;  
 obtaining respective characteristic values for the image characteristics of a block;  
 selecting a transform function from the set of transform functions based on comparisons between said characteristic values and said adjustable thresholds;  
 applying said transform function to the block to form a transformed block;  
 quantizing said transformed block using a quantization value to form a quantized block;  
 selecting an inverse transform function whose application minimally covers said quantized block;  
 inversely quantizing said quantized block to form an inversely quantized block;  
 applying said inverse transform function to said inversely quantized block to form a decoded block;  
 obtaining a quality value for said decoded block for improving images;  
 updating said adjustable thresholds based on said quality value and said characteristic values; and  
 establishing historical records of quality values and characteristic values and associated transform functions and quantization values.

15. The method of claim 14, further comprising:  
 establishing histograms of characteristic values for each of the image characteristics and associated transform functions and quantization values;  
 recording said characteristic values in histograms referenced by said transform function and said quantization value;  
 selecting a statistical function to apply to said histograms;  
 applying said statistical function to said histograms;  
 updating said adjustable thresholds with data from application of said statistical function to said histograms; and

wherein said step of obtaining a quality value further comprises obtaining a peak signal-to-noise ratio for said decoded block.

16. The method of claim 14, further comprising:  
 recording said quality value and characteristic values in historical records referenced by said transform function and said quantization value;  
 selecting a statistical function to apply to said historical records;  
 applying said statistical function to said historical records; and  
 updating said adjustable thresholds with data from application of said statistical function to said historical records.

17. The method of claim 14, wherein said obtaining characteristic values comprises:

obtaining a total energy value;  
 obtaining a horizontal high pass energy value;  
 obtaining a vertical high pass energy value; and  
 obtaining a motion vector magnitude value.

## 14

18. The method of claim 17, wherein said selecting a transform function comprises:

comparing said total energy value to an adjustable total energy threshold;  
 comparing said horizontal high pass energy value to an adjustable horizontal high pass energy threshold;  
 comparing said vertical high pass energy value to an adjustable vertical high pass energy threshold;  
 comparing said motion vector magnitude value to an adjustable motion vector magnitudes threshold; and  
 if, for a given transform function, said total energy value is less than said adjustable total energy threshold, and said horizontal high pass energy value is less than said adjustable horizontal high pass energy threshold, and said vertical high pass energy value is less than said adjustable vertical high pass energy threshold, and said motion vector magnitude value is less than said adjustable motion vector magnitude threshold, then selecting said given transform function.

19. The method of claim 15, wherein said establishing histograms further comprises the steps of:

establishing a total energy histogram;  
 establishing a horizontal high pass energy histogram;  
 establishing a vertical high pass energy histogram; and  
 establishing a motion vector magnitude histogram.

20. The method of claim 19, wherein said selecting a transform function comprises:

comparing said total energy value to an adjustable total energy threshold;  
 comparing said horizontal high pass energy value to an adjustable horizontal high pass energy threshold;  
 comparing said vertical high pass energy value to an adjustable vertical high pass energy threshold;  
 comparing said motion vector magnitude value to an adjustable motion vector magnitudes threshold; and  
 if, for a given transform function, said total energy value is less than said adjustable total energy threshold, and said horizontal high pass energy value is less than said adjustable horizontal high pass energy threshold, and said vertical high pass energy value is less than said adjustable vertical high pass energy threshold, and said motion vector magnitude value is less than said motion vector magnitude threshold, then selecting said given transform function.

21. A processor for coding a block of pixels of a digitized video image using a selectable one of a plurality of coding functions, comprising:

establishment means for establishing adjustable selection criteria used to select a coding function;  
 measurement means for measuring a predetermined characteristic of the block to obtain a characteristic value;  
 selection means for selecting a coding function based on said adjustable selection criteria and said characteristic value;  
 code means for coding the block according to said coding function selected to obtain a coded block;  
 performance means for performing a quality measurement of said coded block;  
 adjustment means for adjusting said adjustable selection criteria for selecting a coding function, utilizing said quality measurement such that quality measurements of subsequent blocks are improved; and  
 establishment means for establishing historical records of quality values and characteristic values and associated coding functions and quantization values.

15

22. A computer-readable medium comprising program instructions for causing a processing system to perform a method to code a block of pixels of a digitized video image using a selectable, one of a plurality of coding functions, the method comprising:

5       establishing adjustable selection criteria for selecting a coding function;

      measuring a predetermined characteristic of the block to obtain a characteristic value;

10       selecting a coding function based on said adjustable selection criteria and said characteristic value;

16

coding the block according to said coding function selected to obtain a coded block;

performing a quality measurement of said coded block;

adjusting said adjustable selection criteria for selecting a coding function, utilizing said quality measurement such that quality measurements of subsequent blocks are improved; and

establishing historical records of quality values and characteristic values and associated coding functions and quantization values.
