(57) **ABSTRACT**

A method for use in the fabrication of a gate electrode includes providing a gate oxide layer and forming a titanium boride layer on the oxide layer. An insulator cap layer is formed on the titanium boride layer and thereafter, the gate electrode is formed from the titanium boride layer. A barrier layer may be formed on the oxide layer prior to forming the titanium boride layer with the gate electrode being formed from the barrier layer and the titanium boride layer. Further, a polysilicon layer may be formed on the gate oxide layer prior to forming the titanium boride layer with the gate electrode being formed from the titanium boride layer and the polysilicon layer. Yet further, a polysilicon layer may be formed on the gate oxide layer and a barrier layer formed on the polysilicon layer prior to forming the titanium boride layer. The gate electrode is then formed from the polysilicon layer, the barrier layer, and the titanium boride layer. Similar methods can further be used in the formation of interconnects to connect contact regions. Gate electrode structures and interconnect structures resulting from the methods are also described. Further, in such methods and structures, the titanium boride layer may be a titanium diboride layer or a titanium boride layer having silicon incorporated therein.

TITANIUM BORIDE GATE ELECTRODE AND INTERCONNECT

This is a division of application Ser. No. 09/634,490, Confirmation No. 8443, filed on Aug. 8, 2000, entitled TITANIUM BORIDE GATE ELECTRODE AND INTERCONNECT (As Amended), U.S. Pat. No. 6,541,830, which is a division of U.S. patent application Ser. No. 08/916,275, filed Aug. 22, 1997, issued as U.S. Pat. No. 6,156,630 on Dec. 5, 2000, which are all incorporated herein by reference.

FIELD OF THE INVENTION

This invention relates to semiconductor fabrication methods and structures resulting from such methods. More particularly, the present invention relates to gate electrode structures and interconnects containing titanium boride and methods for forming such structures.

BACKGROUND OF THE INVENTION

Metal Oxide Semiconductor (MOS) devices are widely used in integrated circuit devices. Such MOS devices may include memory devices which are comprised of an array of memory cells. Each memory cell is comprised of a capacitor, on which the charge stored represents the logical state of the memory cell. Conductors, referred to as word lines, serve as gate electrodes of multiple access transistors which provide access to the memory cells. In a DRAM (Dynamic Random Access Memory), a word line gate electrode typically is fabricated on a p-type silicon substrate coated with a thin film of silicon dioxide, known as the gate oxide. Word lines conventionally are formed on the gate oxide layer as a two-layer stack, typically including polysilicon and a conductor material such as tungsten silicide or titanium silicide (commonly referred to as a polycide word line). Further, polycide structures are also used for local interconnects in MOS devices. For example, such polycide structures may be used for the local interconnection of gates and drains in a SRAM (Static Random Access Memory).

Minimizing resistivity throughout the word line or other interconnect structures is of importance to meet the need of reducing time constants and allowing access of memory cells in as short a time period as possible. As memory density increases, feature sizes, including line sizes, decrease. For example, when the feature size of a conductor, such as a local interconnect or a word line, is reduced in a high density memory, the resistance of the conductor increases. Thin tungsten silicide and titanium silicide are larger grain materials that contribute to a very rough silicide/silicon interface. As such, it reduces the effective ohmic contact area. Therefore, it is desirable to utilize conductors whose resistivity will not significantly increase for the same feature dimensions.

Further, in the fabrication of semiconductor devices, it is desirable to find conductors which are suitable for use at high temperatures (e.g., up to about 1100° C.) during processing steps. Particularly desirable are materials which have low bulk resistivities and good oxidation resistance at high temperatures. However, such materials can be difficult to find, and, once found, difficult to form by conventional methods. Further, other problems may occur with such materials, such as, for example, diffusion of atoms from one layer to another, particularly at high processing temperatures. Such diffusion is particularly undesirable if the properties of one layer are changed because of diffusing atoms.

It has been reported in the article by Choi et al., "Electrical Characteristics of TiB₂ for ULSI Applications," IEEE

Transactions on Electron Devices, Vol. 39, No. 10 (October 1992) that titanium diboride may be used as a diffusion barrier in metallization applications.

In view of the above, there is a need for low resistivity materials for use in gate electrode and interconnect applications. The present invention provides gate electrode structures and interconnect structures which overcome the disadvantages described above, along with other problems as will be apparent from the description below.

SUMMARY OF THE INVENTION

A method for use in the fabrication of a gate electrode according to the present invention includes providing a gate oxide layer and forming a titanium boride layer on the oxide layer. An insulator cap layer is formed on the titanium boride layer and thereafter, the gate electrode is formed from the titanium boride layer.

In one embodiment of gate electrode formation method, a barrier layer is formed on the oxide layer prior to forming the titanium boride layer. The barrier layer is formed of a material selected from refractory silicides and refractory nitrides. Further, the gate electrode is formed from the barrier layer and the titanium boride layer.

In another embodiment of the gate electrode formation method, a polysilicon layer is formed on the gate oxide layer prior to forming the titanium boride layer. The gate electrode is then formed from the titanium boride layer and the polysilicon layer.

In yet another embodiment of the gate electrode formation method, a polysilicon layer is formed on the gate oxide layer and a barrier layer is formed on the polysilicon layer prior to forming the titanium boride layer. The barrier layer is formed of a material selected from refractory silicides and refractory nitrides. Further, the gate electrode is formed from the polysilicon layer, the barrier layer, and the titanium boride layer.

A method for use in the formation of an interconnect in the fabrication of integrated circuits is also described. The method includes providing a substrate assembly including at least two contact regions. A titanium boride layer is formed on the substrate assembly. The interconnect is then formed from the titanium boride layer to connect the at least two contact regions.

In one embodiment of the interconnect formation method, a polysilicon layer is formed on the substrate assembly prior to forming the titanium boride layer. The interconnect is then formed from the titanium boride layer and the polysilicon layer.

In another embodiment of the interconnect formation method, the method includes forming a barrier layer on the substrate assembly prior to forming the titanium boride layer. The barrier layer is formed of a material selected from refractory silicides and refractory nitrides. Further, the interconnect is then formed from the barrier layer and the titanium boride layer.

In yet another embodiment of the interconnect formation method, a polysilicon layer is formed on the substrate assembly and a barrier layer is formed on the polysilicon layer prior to forming the titanium boride layer. The barrier layer is formed of a material selected from refractory silicides and refractory nitrides. Further, the interconnect is then formed from the polysilicon layer, the barrier layer, and the titanium boride layer.

A method of depositing a titanium boride layer for use in the fabrication of integrated circuits according to the present

invention includes providing a chemical vapor deposition reaction chamber containing a substrate assembly. Reactive compounds of titanium, boron and silicon are provided in the reaction chamber. A titanium silicide boride layer is then formed on the substrate assembly by chemical vapor deposition.

A gate electrode structure according to the present invention includes a substrate assembly having a gate oxide region formed thereon. A titanium boride region is formed on the gate oxide region and a cap region is formed on the titanium boride region.

In one embodiment of the gate electrode structure, the polysilicon region is formed between the gate oxide region and the titanium boride region.

In another embodiment of the gate electrode structure, a barrier region is formed between the polysilicon region and the titanium boride region. The barrier region is formed of a material selected from refractory silicides and refractory nitrides.

In yet another embodiment of the gate electrode structure, a barrier region is formed between the gate oxide region and the titanium boride region. The barrier region is formed of a material selected from refractory silicides and refractory nitrides.

An interconnect structure according to the present invention is also described. The structure includes a substrate assembly including at least two contact regions. A titanium boride region is formed on the substrate assembly connecting the at least-two contact regions.

In one embodiment of the interconnect structure, a polysilicon region is formed between the substrate assembly and the titanium boride region.

In another embodiment of the interconnect structure, a barrier region is formed between the polysilicon region and the titanium boride region. The barrier region is formed of a material selected from refractory silicides and refractory nitrides.

In yet another embodiment of the interconnect structure, a barrier region is formed between the substrate assembly and the titanium boride region. The barrier region is formed of a material selected from refractory silicides and refractory nitrides.

In the methods and structures generally described above, the titanium boride layer may be a titanium diboride layer or a titanium boride layer having silicon incorporated therein.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is an illustrative diagram of one embodiment in accordance with the present invention showing layers formed on a substrate assembly.

FIG. 2 is an illustrative diagram of the layers shown in FIG. 1 patterned in accordance with the present invention.

FIG. 3 is an illustrative diagram of an alternative embodiment of the present invention showing layers formed on a substrate assembly after patterning.

FIG. 4 is an illustrative diagram of another alternative embodiment of the present invention showing layers formed on a substrate assembly after patterning.

FIG. 5 is an illustrative diagram of yet another alternative embodiment of the present invention showing layers on a substrate assembly after patterning.

FIG. 6 is a general schematic illustration of a chemical vapor deposition system.

FIG. 7 is a general schematic illustration of a memory circuit of which gate electrodes and interconnects can be formed in accordance with the present invention.

FIGS. 8A–8C are illustrative diagrams showing use of the present invention in the fabrication of a word line gate electrode.

FIGS. 9A and 9B are illustrative diagrams showing use of the present invention in fabrication of a local interconnect.

DETAILED DESCRIPTION OF THE EMBODIMENTS

The present invention shall be generally described with reference to FIGS. 1–9. With the description as provided below, it is readily apparent to one skilled in the art that the various processes described with reference to the figures may be utilized in various configurations. For example, the present invention may be used in the formation of word lines, bit lines, local interconnects, etc. for various memory circuits. Further, for example, the present invention may be particularly beneficial in the fabrication of word line gate electrodes of DRAM's or for local interconnects of SRAM's.

In this application, “semiconductor substrate” refers to the base semiconductor layer, e.g., the lowest layer of silicon material in a wafer or a silicon layer deposited on another material such as silicon on sapphire. The term “semiconductor substrate assembly” refers to the semiconductor substrate having one or more layers or structures formed thereon. When reference is made to a substrate assembly in the following description, various process steps may have been previously utilized to form regions/junctions in the semiconductor substrate thereof. It should be apparent that scaling in the figures does not represent precise dimensions of the various elements illustrated therein.

As described in further detail with reference to FIG. 1, an optional doped polysilicon layer **20**, optional barrier layer **22**, titanium boride layer **24** and an insulator cap layer **26** are deposited sequentially over the substrate assembly **10**. The stack may be formed on any semiconductor substrate or substrate assembly. For example, the underlayer over which the stack is formed (i.e., the upper portion of the substrate assembly **10**) may be a gate oxide for forming a word line gate electrode as further described herein or may include an oxide and/or a silicon containing region in the formation of a local interconnect.

As indicated above, and as further shown in the illustrative embodiment of FIG. 8, the underlying layer, i.e., the upper region of the substrate assembly **10** may be a gate oxide layer. The gate oxide layer may be formed, for example, by thermal oxidation of silicon. The gate oxide is typically a thin layer, e.g. about 40 Å to about 150 Å. In general, the gate oxide functions as a dielectric whose thickness is chosen specifically to allow induction of a charge in the gate region.

If used, the optional layer of polysilicon **20** may be formed on the substrate assembly **10** by any known method for forming such a polysilicon layer. For example, polysilicon layer **20** may be formed by the pyrolytic decomposition of a silane at temperatures ranging from about 550° C. to about 650° C. Preferably, the polysilicon layer ranges in thickness from about 200 Å to about 2000 Å. The polysilicon layer **20** is a polycrystalline layer of silicon which is doped with, for example, phosphorous (i.e., to form n-doped Si), such as by ion implantation.

If used, the optional barrier layer **22** is formed over the polysilicon layer **20** (or over the substrate assembly **10** as shown in FIG. 3). The optional barrier layer **22** includes a refractory silicide or refractory nitride formed by any known method for forming the particular desired silicide or nitride.

For example, a refractory metal is first deposited by sputtering, evaporation, or chemical vapor deposition (CVD). The desired silicide or nitride is obtained by controlling reaction conditions as is known to one skilled in the art. For example, when metal deposition is followed by annealing in a nitrogen atmosphere, a metal nitride is produced. Alternatively, for example, depending on the temperature of the annealing step, the metal reacts with silicon in adjacent layers (e.g., the polysilicon layer) to form a silicide. Further, for example, the silicide may be sputtered from a silicide target. Suitable refractory metals to produce such silicides or nitrides include but are not limited to cobalt, nickel, tungsten, tantalum, and titanium, resulting in, for example, WSiN, TaN, WSi₂, TiN, TiSi₂, CoSi₂, and WN. As indicated in the resulting nitrides and silicides, the barrier layer may also be a refractory silicide nitride resulting from various known processes. The optional barrier layer **22** ranges in thickness from about 25 Å to about 500 Å, preferably the thickness ranges from about 25 Å to about 200 Å. The optional barrier layer **22** is used to retard interdiffusion and resist the tendency for chemical reactions to form new phases between adjoining materials which the barrier separates. For example, the diffusion barrier layer **22** retards diffusion of boron from the titanium boride layer into adjacent layers.

The titanium boride layer **24** is then formed via chemical vapor deposition (CVD) processing. For example, the titanium boride layer **24** may be formed with use of a thermal CVD process or via a plasma CVD process in which compounds containing titanium and boron react in the gas phase. The titanium boride layer **24** may be any layer including titanium and boron. Preferably, the titanium boride layer **24** is substantially stoichiometric titanium diboride (TiB₂) or the titanium boride layer **24** may be TiSi_xB_y, where x is in the range of 0 to about 0.2 and y is in the range of about 1.8 to 2.0. The presence of silicon is believed to enhance the oxidation resistance of the titanium boride layer **24** at elevated temperatures.

The titanium boride layer **24** preferably ranges in thickness from about 200 Å to about 3000 Å. However, the thickness of the titanium boride layer **24** depends on the ultimate desired application of the layer because the thickness corresponds to the resistivity of the layer. For example, for a gate electrode, the titanium boride layer may have a thickness of about 300 Å to about 3000 Å, and for use in a local interconnect the thickness may be in the range of about 500 Å to about 2000 Å.

The CVD processes used to deposit the titanium boride layer **24** is described in further detail below. Generally, as further described below, the source for the titanium is a titanium halide, the source for the boron is a borane, and the source of silicon in the CVD process is a gaseous silane.

Finally, an optional cap layer **26** is formed on the titanium boride layer **24**. The optional insulator cap layer **26** is preferably an oxide or a nitride which is formed in accordance with known methods for forming such layers. For example, the cap layer may be formed by CVD, thermal oxidation, or by any other known method. In the fabrication of a word line gate electrode, the cap layer **26** is typically used. On the other hand, in the fabrication of a local interconnect, the cap layer **26** may not be used. Further, in the fabrication of a word line gate electrode, the cap layer **26** is an insulating layer, such as, for example, silicon nitride, SiO_xN_y, or an oxide, such as, for example, BPSG, silicon dioxide, TEOS, etc. The optional cap layer **26** is formed on the titanium boride layer **24** and ranges in thickness, preferably from about 200 Å to about 3000 Å.

After the cap layer **26** has been formed, the layered structure shown in FIG. 1 is patterned and etched as required for the desired application. First, a photoresist is coated onto the cap layer **26** and patterned using photolithographic techniques known in the art. For example, ultraviolet radiation may be passed through a mask so that a desired pattern is imaged on the photoresist. This causes changes in the solubility of the exposed areas of the photoresist, such that after development with a suitable solvent, a desired pattern is fixed on the structure. The photoresist may then be baked to enable it to withstand subsequent processing. The above process results in a patterned photoresist mask.

Once the patterned mask is formed, the structure to be formed can be etched by methods known in the art and selected to produce the best results with the layers used in the structure. The etching is preferably performed by dry etching techniques. Endpoint detection can be accomplished by techniques known in the art, such as with optical or chemical endpoint detection. For example, the cap layer may be etched with fluorine chemistry, the titanium boride layer may be etched with a chlorine chemistry in a reactive ion chamber, and the polysilicon may be etched with a chlorine and hydrogen bromide chemistry. It should be apparent to one skilled in the art that any known etching techniques suitable for etching the particular layers may be used in accordance with the present invention. After completion of etching one or more of the desired layers to result in the desired structure, the photoresist is removed by, for example, an oxygen ash or an ozone plasma.

FIG. 2 illustrates the results after patterning and etching for one embodiment of the invention. In this embodiment, a cap layer **26**, titanium boride layer **24**, barrier layer **22**, and polysilicon layer **20** are used and such layers are etched down to the substrate assembly **10**, e.g., such as to a gate oxide layer, to form a gate electrode structure.

FIG. 3 illustrates another embodiment of the invention after patterning and etching. In this embodiment, a cap layer **26**, titanium boride layer **24**, and optional barrier layer **22** are used and are etched down to the substrate assembly **10** to form a structure for use in the fabrication of an integrated circuit, e.g., an interconnect, a gate electrode, etc. For example, the cap layer **26** may have a thickness in the range of about 500 Å to about 3000 Å, the titanium boride layer **24** may have a thickness in the range of about 300 Å to about 2000 Å, and the optional barrier layer **22** may have a thickness in the range of about 100 Å to about 300 Å.

FIG. 4 illustrates yet another embodiment of the invention after patterning and etching. In FIG. 4, a cap layer **26** and titanium boride layer **24** are used and are etched down to the substrate assembly **10** to form the desired structure. For example, the cap layer **26** may have a thickness in the range of about 500 Å to about 3000 Å and the titanium boride layer **24** may have a thickness in the range of about 300 Å to about 2000 Å. In this embodiment, a barrier layer is not used indicating that diffusion of boron into adjacent layers is not always problematic. Thus, a barrier layer is not always necessary when forming the structures described herein.

FIG. 5 illustrates yet another embodiment of the invention after patterning and etching. As shown in, FIG. 5, a cap layer **26**, titanium boride layer **24**, and polysilicon layer **20** are used and are etched down to the substrate assembly **10** having a gate oxide layer **19** to obtain the desired structure, e.g., a gate electrode. For example, the cap layer **26** may have a thickness in the range of about 500 Å to about 3000 Å, the titanium boride layer **24** may have a thickness in the range of about 300 Å to about 2000 Å, the polysilicon layer

20 may have a thickness in the range of about 500 Å to about 2000 Å, and the gate oxide **19** may have a thickness in the range of about 40 Å to about 150 Å.

FIG. 6 shows a CVD system which is to be taken as a general illustration representative of both a thermal CVD system and a plasma CVD system which may be used in accordance with the present invention. As would be apparent to one skilled in the art, the thermal system would not use components needed for generating a plasma in the reaction chamber. With reference to FIG. 6, the formation of the titanium boride layer **24** shall be described.

In the practice of the present invention, suitable titanium containing and boron containing compounds are chosen which will react to form titanium diboride, or, for the formation of $TiSi_xB_y$, such suitable titanium and boron containing compounds and further a silicon containing reactant is chosen for reaction in the reaction chamber. Suitable titanium containing compounds include titanium compounds which are volatile at room temperature or when heated, such as titanium halides. A preferred titanium compound is titanium tetrachloride. Suitable boron-containing compounds include borane compounds of the formula B_nH_{n+4} , such as B_2H_6 (diborane). The dihydroboranes, of formula B_nH_{n+6} , may also be suitable for practice of this invention. Suitable silicon containing compounds include silanes such as SiH_4 and Si_2H_6 .

For example, titanium diboride (TiB_2) may be deposited by either a thermal or plasma CVD process according to the following reaction:

Optionally, silicon may be incorporated into the titanium boride. This is performed by introducing a silane into the reaction mixture. With the introduction of a silane into the reaction mixture, titanium silicide boride forms according to the following reaction:

The amount of silicon in the titanium boride layer increases its bulk resistivity, which is usually not desirable. However, this undesirable characteristic is offset by an increase in the oxidation resistance of this layer at high temperatures. The oxidation resistance is particularly beneficial for subsequent processing. For example, such oxidation resistance is beneficial when the structure including titanium silicide boride is part of a gate electrode structure subjected to reoxidation of source and drain.

For either thermal CVD or plasma enhanced CVD processes, the reactive compounds are admitted as gases into the reaction chamber which is at low pressure (i.e., low compared to ambient pressure). The reaction chamber is evacuated by means of vacuum pumps to remove undesirable reactive species, such as oxygen. Then, carrier gas and reactive compounds are admitted into the chamber. This is accomplished by one of various techniques. For example, the introduction into the chamber may be accomplished with the use of compounds which are gases at room temperature or by heating a volatile compound and bubbling a gas through it to carry it into the reaction chamber. It should be readily apparent that the techniques used for introduction of the compounds into the chamber may be varied and that the present invention is not limited to any particular technique.

For example, in accordance with the present invention, a volatile compound containing titanium (e.g., $TiCl_4$) is heated and/or a carrier gas such as argon or helium is used to bubble through the titanium compound and introduce the compound

into the reaction chamber. In furtherance of this example, an inert gas, such as argon or helium, is bubbled through titanium chloride at a rate of about 20 sccm to about 500 sccm (standard cc/min). A boron containing compound (e.g., B_2H_6) is admitted into the reaction chamber at a flow rate ranging from about 20 sccm to about 1000 sccm. Typically, the reactive gases are admitted at separate inlet ports. In addition to the reactive compound, a dilution gas is flowed into the chamber. For example, argon may be flowed through the chamber at a flow rate ranging from about 100 sccm to about 10,000 sccm. The dilution gas, such as argon, serves as a carrier gas, to dilute reactant gases, to help control the desired deposition pressure, and to assist in removing reaction by-products from the reaction chamber. The temperature in the reaction chamber during the reactive deposition ranges from about 300° C. to about 800° C. depending on the type of CVD used. For example, for thermal CVD, the temperatures will be at the higher end of the range, e.g., about 500° C. to about 800° C., and for the plasma CVD process, the temperature range will be somewhat lower, e.g., about 300° C. to about 700° C. The pressure of the reaction chamber preferably ranges from about 0.5 torr to about 10 torr.

The reaction of the titanium containing compounds and boron containing compounds is carried out for a time sufficient to deposit the desired thickness of the titanium diboride layer on the underlying surface. The reaction conditions for the deposition of titanium silicide boride are substantially the same as those described above for titanium diboride, except that a silane is admitted into the reaction chamber at a flow rate of about 10 sccm to about 500 sccm.

In plasma enhanced CVD, a plasma is created by applying an electric field across the gas mixture containing the carrier gas and reactants. The plasma adds energy to the reaction to drive the reaction to completion. Generally, use of a plasma process allows the substrate assembly to be kept at a somewhat lower temperature than other CVD processes which is a processing advantage. For example, the temperatures are preferably in the range of about 300° C. to about 700° C.

Any suitable power source may be used to generate the plasma in the reaction chamber. Suitable power sources include an RF generator, a microwave (e.g., 2.5 GHz microwave source) generator, or an electron cyclotron resonance (ECR) source. A preferred power source is an RF generator operating as a standard 13.56 MHz source. The RF power preferably ranges from about 100 watts to about 5 kilowatts.

As generally shown in FIG. 6 for illustrative purposes only, in plasma enhanced CVD, gaseous reactants **81** and **82** enter the reaction chamber **80** through controller and shower head **84**. For example, in the deposition of titanium diboride the reactants would include a titanium containing compound and a boron containing compound as previously described. Further, for example, in the deposition of titanium silicide boride, the reactants would further include a silicon containing compound. An RF generator **88** supplies power between the substrate holder **86** and the reaction chamber **80**, thus creating a plasma in the region above the wafer **85**. The reactant gases begin to react inside the reaction chamber **80** as they are absorbed at the heated surface of the substrate wafer **85**. The wafer **85** is heated by convection from substrate holder **86** (such as graphite or alumina) that is heated to a preferred temperature of, for example, about 300° C. to about 800° C. via a lamp source **87**. A chemical reaction occurs, thereby depositing a layer of titanium boride on the surface of the wafer **85**. The reaction is enhanced by the presence of the plasma, which serves to

increase the deposition rate. A constant deposition pressure between about 0.5 torr and 10 torr is monitored and maintained by conventional pressure control components; i.e., pressure sensor **89**, pressure switch **90**, air operating vacuum valve **91** and pressure control valve **92**. The reaction by-product, HCl, and carrier gas pass through particulate filter **93** and escape through exhaust vent **94**.

In a thermal CVD process, gaseous reactants and carrier gas are admitted into a reaction chamber typically via separate inlet ports. FIG. **8** is also useful in understanding the thermal CVD process, except that in thermal CVD, there is no power generator **88** and therefore no plasma during the deposition. The reaction chamber **80** is at reduced pressure (preferably, about 0.5 torr to about 10 torr). The substrate is heated to a temperature of about 300° C. to about 800° C. Reaction takes place on or near the surface of a substrate assembly, e.g., wafer, forming the desired layer of material, e.g. titanium silicide boride. Carrier gas assists the movement of reactive gases through the chamber and of by-products out of the chamber. The reaction is carried out for the time sufficient to deposit the desired thickness of the titanium boride layer on the underlying surface.

The processes described above are particularly useful for fabrication of word line gate electrodes and local interconnect applications, such as for DRAMs and SRAMs. For example, as shown in schematic illustration of a memory circuit **100** (FIG. **7**), various portions of the circuit may be fabricated using the processes described above. The memory circuit **100** includes six transistors **102–107** connected in various manners to other elements such as with strap lines **109** and **111**. Further, the schematic illustration shows word line gate electrodes at reference numbers **113** and **114** with bit line connections at reference numbers **116** and **117**. It should be readily apparent from the description above and the description to follow that any number of the connections or structures necessary for providing a circuit, such as circuit **100**, can be advantageously formed using the methods as described herein. For example, the processes are beneficial for providing the strap lines **109** and **111** for connection of the gate electrode to source/drain regions, for providing word line gate electrode **113** and **114**, or for providing other structures such as buried digit lines or any other structure requiring low resistive material capable of withstanding oxidation conditions.

FIGS. **8** and **9** generally show the processes used in several illustrative embodiments. However, it should be readily apparent to one skilled in the art that the processes described above can be used for various other applications. Therefore, it is recognized that the following embodiments are for illustration only and not to be read as unduly limiting to the scope of the present invention.

FIGS. **8A–8C** illustrate fabrication of a word line gate electrode (FIG. **8C**) in a memory device. FIG. **8A** includes field oxide regions **162** formed on substrate **160** such as, for example, by conventional local oxidation of silicon (LOCOS) processing. Further, a gate insulating layer, i.e., a gate oxide **164**, is formed on semiconductor substrate **160** in the active area formed by field oxide regions **162**. Semiconductor substrate **160** refers to the base semiconductor layer, e.g., a base layer of silicon material of the device or wafer or a silicon layer formed on another material such as silicon on sapphire.

As shown in FIG. **8B**, a layer of polysilicon **166** is formed over the field oxide regions **162** and gate oxide **164**. The polysilicon layer **166** can be formed by any conventionally known method, such as by chemical vapor deposition or by growth of polysilicon. A barrier layer **168** is then formed

over the polysilicon layer **166**. Thereafter, as previously described herein, a layer of titanium boride **170** and a cap layer **174** are formed sequentially over the barrier layer **168**. Thereafter, as generally described herein, the polysilicon layer **166**, the barrier layer **168**, the titanium boride layer **170** and the cap layer **174** are patterned resulting in the gate electrode structure at least in part over the gate oxide **164** in the active area of the memory device as shown in FIG. **8C**. Thereafter, various process steps are performed, such as reoxidation of the source and drain regions **178** and **179**, spacer formation, and other subsequent processing as readily known to one skilled in the art.

FIGS. **9A** and **9B** illustrate fabrication of a local interconnect such as for an SRAM device. FIG. **9A** shows field oxide regions **182** formed on substrate **180** isolating an active area wherein source region **187** and drain region **185** are formed such as by implantation after formation of gate structure **186**. The gate structure **186** includes polysilicon region **192** and metal silicide region **193** of the gate electrode, and further includes spacers **197** and gate oxide **191**. A conductive line **184** is also formed including polysilicon region **188** and metal silicide region **190** with spacers **196** formed at the sides thereof. At the surface of this particular structure, a local interconnect **200** (FIG. **9B**) is formed for connecting the drain **185** to the line **184**.

As shown in FIG. **9A**, a polysilicon layer **194** is formed over the various device structures. Thereafter, a barrier layer **195** is formed over the polysilicon layer **194** and titanium boride layer **199** is formed over the barrier layer **195**. Photolithography is utilized to pattern the polysilicon layer **194**, the barrier layer **195**, and the titanium boride layer **199** resulting in the local interconnect **200** as shown in FIG. **9B** connecting the drain **185** to the line **184**.

It is readily apparent that the local interconnect can be formed to connect various elements of the structure of a device and that the present invention is in no manner limited to the illustration shown in FIGS. **9A–9B**. For example, a local interconnect may be made between various regions of one or more device structures, e.g., connection of a source and drain of a pair of transistors.

The above two illustrations were described with use of all the optional layers being used as shown in FIGS. **1** and **2**. The stacks shown and used in the other embodiments as shown in FIGS. **3–5** could also have been used as should be readily apparent.

Although the invention has been described above with particular reference to various embodiments thereof, variations and modifications of the present invention can be made within a contemplated scope of the following claims.

What is claimed is:

1. An interconnect structure, comprising:
 - a substrate assembly including at least two contact regions;
 - a local interconnect consisting essentially of titanium boride formed on the substrate assembly connecting the at least two contact regions.
2. The structure of claim **1**, wherein the titanium boride region consists essentially of titanium diboride.
3. The structure of claim **1**, wherein the two contact regions comprise a gate electrode and a source/drain region.
4. An interconnect structure comprising:
 - a substrate assembly including at least two contact regions; and
 - a local interconnect connecting the at least two contact regions, wherein the local interconnect comprises:
 - a polysilicon region formed on the substrate assembly,
 - and

11

a titanium boride region formed on the polysilicon region.

5. The structure of claim 4, wherein the two contact regions comprise a gate electrode and a source/drain region.

6. The structure of claim 4, wherein the titanium boride region is a titanium diboride region.

7. An interconnect structure comprising:

a substrate assembly including at least two contact regions; and

a local interconnect to connect the at least two contact regions, wherein the local interconnect consists essentially of:

a barrier region formed on the substrate assembly, wherein the barrier region is formed of at least one of a refractory silicide and a refractory nitride; and a titanium boride region formed on the barrier region.

8. The structure of claim 7, wherein the two contact regions comprise a gate electrode and a source/drain region.

9. The structure of claim 7, wherein the titanium boride region is a titanium diboride region.

10. An interconnect structure comprising:

a substrate assembly including at least two contact regions; and

an interconnect to connect the at least two contact regions, the interconnect comprising:

a polysilicon region formed on the substrate assembly, a barrier region formed on the polysilicon region, wherein the barrier region comprises at least one of a refractory silicide and a refractory nitride, and a titanium boride region formed on the barrier region.

11. The structure of claim 10, wherein the barrier region comprises at least one of tungsten silicide, titanium nitride, tungsten nitride, tantalum nitride, and WSiN.

12. The structure of claim 10, wherein the two contact regions comprise a gate electrode and a source/drain region.

12

13. An interconnect structure comprising:

a substrate assembly including at least two contact regions; and

a local interconnect consisting essentially of titanium silicide boride to connect the at least two contact regions.

14. An interconnect structure comprising:

a substrate assembly including at least two contact regions;

an interconnect to connect the at least two contact regions, the interconnect comprising a titanium silicide boride region formed on the substrate assembly, wherein the titanium silicide boride region comprises $TiSi_xB_y$, where x is in the range of 0 to about 0.2 and y is in the range of about 1.8 to 2.0.

15. The structure of claim 14, further comprising a polysilicon region formed between the substrate assembly and the titanium silicide boride region.

16. The structure of claim 14, further comprising a barrier region formed between the substrate assembly and the titanium silicide boride region, the barrier layer comprises at least one of a refractory silicide and a refractory nitride.

17. The structure of claim 14, further comprising a polysilicon region formed on the substrate assembly and a barrier region formed between the polysilicon region and the titanium silicide boride region, wherein the barrier layer comprises at least one of a refractory silicide and a refractory nitride.

18. The structure of claim 17, wherein the barrier layer comprises at least one of tungsten silicide, titanium nitride, tungsten nitride, tantalum nitride, and WSiN.

19. The structure of claim 14, wherein the two contact regions comprise a gate electrode and a source/drain region.
