(57) **ABSTRACT**

A plasma reactor includes a vacuum enclosure including a side wall and a ceiling defining a vacuum chamber, and a workpiece support within the chamber and facing the ceiling for supporting a planar workpiece, the workpiece support and the ceiling together defining a processing region between the workpiece support and the ceiling. Process gas inlets furnish a process gas into the chamber. A plasma source power electrode is connected to an RF power generator for capacitively coupling plasma source power into the chamber for maintaining a plasma within the chamber. The reactor further includes at least a first overhead solenoidal electromagnet adjacent the ceiling, the overhead solenoidal electromagnet, the ceiling, the sidewall and the workpiece support being located along a common axis of symmetry. A current source is connected to the first solenoidal electromagnet and furnishes a first electric current in the first solenoidal electromagnet whereby to generate within the chamber a magnetic field which is a function of the first electric current, the first electric current having a value such that the magnetic field increases uniformity of plasma ion density radial distribution about the axis of symmetry near a surface of the workpiece support.

**CAPACITIVELY COUPLED PLASMA  
REACTOR WITH MAGNETIC PLASMA  
CONTROL**

This application claims priority of U.S. Provisional Application Ser. No. 60/383,194, filed May 22, 2002 entitled, "CAPACITIVELY COUPLED PLASMA REACTOR WITH MAGNETIC PLASMA CONTROL," by Daniel Hoffman, et al.

**BACKGROUND**

Capacitively coupled plasma reactors are used in fabricating semiconductor microelectronic structures with high aspect ratios. Such structures typically have narrow, deep openings through one or more thin films formed on a semiconductor substrate. Capacitively coupled plasma reactors are used in various types of processes in fabricating such devices, including dielectric etch processes, metal etch processes, chemical vapor deposition and others. Such reactors are also employed in fabricating photolithographic masks and in fabricating semiconductor flat panel displays. Such applications depend upon plasma ions to enhance or enable desired processes. The density of the plasma ions over the surface of the semiconductor workpiece affects the process parameters, and is particularly critical in the fabrication of high aspect ratio microelectronic structures. In fact, a problem in fabricating high aspect ratio microelectronic integrated circuits is that non-uniformities in the plasma ion density across the workpiece surface can lead to process failure due to non-uniform etch rates or deposition rates.

A typical capacitively coupled reactor has a wafer support pedestal in the reactor chamber and a ceiling overlying the wafer support. The ceiling may include a gas distribution plate that sprays process gas into the chamber. An RF power source is applied across the wafer support and ceiling or wall to strike and maintain a plasma over the wafer support. The chamber is generally cylindrical, while the ceiling and wafer support are circular and coaxial with the cylindrical chamber to enhance uniform processing. Nevertheless, such reactors have non-uniform plasma density distributions. Typically, the radial density distribution of plasma ions is high over the center of the wafer support and low near the periphery, a significant problem. Various approaches are used to control the plasma ion density distribution so as to improve process uniformity across the wafer or workpiece surface, and at least partially overcome this problem.

One such approach is to provide a set of magnetic coils spaced circumferentially around the side of the reactor chamber, the coils all facing the center of the chamber. A relatively low frequency sinusoidal current is supplied to each coil, the sinusoidal currents in adjacent coils being offset in phase so as to produce a slowly rotating magnetic field over the wafer support. This feature tends to improve the radial distribution of plasma ion density over the wafer support. Where this approach is employed in reactive ion etching, it is called magnetically enhanced reactive ion etching (MERIE). This approach has certain limitations. In particular, the strength of the magnetic field may need to be limited in order to avoid device damage to microelectronic structures on the semiconductor workpiece associated with the strength of the magnetic field. The strength must also be limited to avoid chamber arcing associated with the rate of change of magnetic field strength. As a result, the total MERIE magnetic field may need to be substantially reduced and therefore may face substantial limitations in plasma ion density uniformity control.

Another approach is called configurable magnetic fields (CMF) and employs the same circumferentially spaced coils referred to above. But, in CMF the coils are operated so as to impose a magnetic field that extends across the plane of the workpiece support, from one side to the other. In addition, the magnetic field rotates about the axis of the wafer support, to produce a time-averaged magnetic field that is radial. This is all accomplished, in the case of a reactor having four side-by-side coils, by furnishing one D.C. current to one pair of adjacent coils and a different (or opposite) D.C. current to the opposite pair of adjacent coils. The coils are switched to rotate this pattern so that the magnetic field rotates, as mentioned above. This approach is vulnerable to chamber or wafer arcing problems due to the abrupt switching of the CMF magnetic fields, and therefore the magnetic field strength must be limited. As a result, in some applications the magnetic field cannot be sufficient to compensate for plasma ion density non-uniformities produced by the reactor.

Thus, what is needed is a way of compensating for plasma ion density distribution non-uniformities more efficiently (so that the magnetic field strength can be less) and with less (or with no) time fluctuations in the magnetic field.

**SUMMARY**

A plasma reactor includes a vacuum enclosure including a side wall and a ceiling defining a vacuum chamber, and a workpiece support within the chamber and facing the ceiling for supporting a planar workpiece, the workpiece support and the ceiling together defining a processing region between the workpiece support and the ceiling. Process gas inlets furnish a process gas into the chamber. A plasma source power electrode is connected to an RF power generator for capacitively coupling plasma source power into the chamber for maintaining a plasma within the chamber. The reactor further includes at least a first overhead solenoidal electromagnet adjacent the ceiling, the overhead solenoidal electromagnet, the ceiling, the sidewall and the workpiece support being located along a common axis of symmetry. A current source is connected to the first solenoidal electromagnet and furnishes a first electric current in the first solenoidal electromagnet whereby to generate within the chamber a magnetic field which is a function of the first electric current, the first electric current having a value such that the magnetic field increases uniformity of plasma ion density radial distribution about the axis of symmetry near a surface of the workpiece support.

**BRIEF DESCRIPTION OF THE DRAWINGS**

FIGS. 1A, 1B and 1C illustrate a plasma reactor with an overhead VHF electrode and overhead coils for controlling plasma ion uniformity.

FIG. 2 illustrates an exemplary apparatus for controlling the overhead coils of FIG. 1.

FIGS. 3A and 3B are graphical representations of a magnetic field of the overhead coils of FIG. 1 and FIG. 3C is a spatial representation of the same field.

FIGS. 4A, 4B, 4C and 4D are graphs of the etch rate (vertical axis) on the wafer surface as a function of radial location (horizontal axis) for various modes of operation of the reactor of FIG. 1.

FIGS. 5A, 5B, 5C and 5D are graphs of the etch rate (vertical axis) on the wafer surface as a function of radial location (horizontal axis) for further modes of operation of the reactor of FIG. 1.

FIG. 6 is a graph depicting etch rate as a function of magnetic field.

FIGS. 7 and 8 illustrate the reactor of FIG. 1A with MERIE magnets.

FIG. 9 depicts a method of operating the reactor of FIG. 1A.

FIG. 10 is a graph illustrating a comparative example of magnetic pressure and ion or electron density as functions of radial location on the wafer surface in the reactor of FIG. 1A.

FIG. 11 is a graph depicting etch rate non-uniformity as a function of coil current.

FIG. 12 illustrates radial ion distribution at zero coil current in the example of FIG. 11.

FIGS. 13A and 13B compare measured and predicted etch rate distributions at a coil current of about 11 amperes in the example of FIG. 11.

FIGS. 14A and 14B compare measured and predicted etch rate distributions at a coil current of about 35 amperes in the example of FIG. 11.

FIG. 15 depicts a further method of operating the reactor of FIG. 1A.

FIG. 16 illustrates a magnetic field distribution obtained in a reactor corresponding to FIG. 1A.

FIG. 17 depicts the gradient of the square of the magnetic field of FIG. 16 in the wafer plane.

FIG. 18 illustrates another magnetic field distribution obtained in a reactor corresponding to FIG. 1A.

FIG. 19 depicts the gradient of the square of the magnetic field of FIG. 18 in the wafer plane.

FIG. 20 illustrates a yet further magnetic field distribution obtained in a reactor corresponding to FIG. 1A.

FIG. 21 depicts the gradient of the square of the magnetic field of FIG. 20 in the wafer plane.

FIG. 22 depicts yet another method of operating the reactor of FIG. 1A.

FIG. 23 illustrates an exemplary microcontroller operation for controlling the reactor of FIG. 1A.

FIG. 24 illustrates a plasma reactor including features contained in the reactor of FIG. 1A.

FIG. 25 illustrates another plasma reactor including features contained in the reactor of FIG. 1A.

FIGS. 26, 27, 28, 29A and 29B illustrate a gas distribution plate for the reactors of FIGS. 1A, 24 and 25.

FIGS. 30 and 31 illustrate thermal control features in gas distribution plate like that of FIG. 26.

FIGS. 32 and 33 illustrate a gas distribution plate corresponding to FIG. 26 having dual zone gas flow control.

FIG. 34 illustrates a plasma reactor corresponding to FIG. 1A having the dual zone gas distribution plate.

FIGS. 35 and 36 illustrate exemplary dual zone gas flow controllers.

FIG. 37 illustrates a plasma reactor corresponding to FIG. 34 having three overhead coils for controlling plasma ion distribution.

FIGS. 38 and 39 depict different gas injection hole patterns in the gas distribution plate of FIG. 26 for producing center low or center high gas flow distributions, respectively.

FIGS. 40, 41, 42 and 43 illustrate different arrangements of overhead coils for controlling plasma ion distribution.

FIGS. 44 and 45 illustrate a plasma reactor corresponding to FIG. 1A in which the overhead coils are replaced by upper

and lower magnetic coils above and below the reactor chamber to produce a cusp-shaped magnetic field best seen in FIG. 45.

FIG. 46 illustrates how the upper and lower coils of FIGS. 44 can be replaced by configurable magnetic field (CMF) coils operated in such a manner as to produce the cusp-shaped magnetic field of FIG. 45.

FIGS. 47A–47D illustrate a mode of operation of the CMF coils of FIG. 46 to produce a desired magnetic field configuration.

FIGS. 48, 49 and 50 illustrate an annular apertured plate in the reactor of FIG. 1A for preventing plasma ions from entering the reactor's pumping annulus.

FIG. 51 illustrates a rectangular version of the reactor of FIG. 1A for processing rectangularly shaped workpieces.

FIG. 52 illustrates a reactor corresponding to FIG. 1A having a retractable workpiece support pedestal.

#### DETAILED DESCRIPTION

The plasma ion density distribution exhibited by a particular plasma reactor is a function of chamber pressure, gas mixture and diffusion, and source power radiation pattern. In the present invention, this distribution is magnetically altered to approximate a selected or ideal distribution that has been predetermined to improve process uniformity. The magnetically altered or corrected plasma ion density distribution is such that process uniformity across the surface of the wafer or workpiece is improved. For this purpose, the magnetically corrected plasma distribution may be non-uniform or it may be uniform, depending upon the needs determined by the user. We have discovered that the efficiency with which an average magnetic field strength exerts pressure on a plasma to change its distribution to a desired one can be improved. This surprising result can be achieved in accordance with this discovery by increasing the radial component of the gradient of the magnetic field. The radial direction is understood to be about the axis of symmetry of the cylindrical chamber. Thus, what is needed is a magnetic field configuration which has a large radial gradient and a small field strength in other directions. Such a magnetic field is cusp-shaped with its axis of symmetry coinciding with the axis of the cylindrical reactor chamber. One way of producing a cusp-shaped magnetic field is to provide coils above and below the cylindrical chamber and run D.C. currents through these coils in opposite directions.

Depending upon the chamber design, it may be impractical to provide a coil below the wafer pedestal, and therefore in a first case, a top coil suffices for these purposes. In addition, what is needed is for the cusp-shaped magnetic field to be configurable or adjustable for accurate control or alteration of a plasma ion distribution inherent in a given plasma reactor chamber (the "ambient" plasma ion distribution). Since the plasma ion distribution provided in different capacitively coupled reactors can vary widely, such adjustability may be essential in some cases. The radial component of the magnetic field gradient is chosen to apply the magnetic pressure required to alter the ambient distribution to the desired distribution. For example, if the desired distribution is a uniform distribution, then the applied magnetic field is selected to counteract the non-uniformity in the radial distribution of plasma ion density exhibited by the reactor in the absence of the magnetic field. In this case, for example, if the reactor tends to have a center-high distribution of plasma ion density, then the magnetic field gradient is chosen to sustain the plasma density over the center of the wafer support pedestal and enhance it near the periphery to achieve uniformity.

Such adjustability of the cusp-shaped magnetic field is achieved in accordance with our discovery by providing at least a second overhead coil of a different (e.g., smaller) diameter than the first coil. The D.C. currents in the respective coils are independently adjustable so as to permit configuration of the cusp-shaped magnetic field in a highly flexible manner to alter virtually any ambient plasma ion distribution to approximate some desired plasma ion distribution. This choice of field configuration can be designed to modify center-high or center-low plasma ion density distributions.

One advantage that can be realized is two-fold, in that the cusp-shaped magnetic field has a large radial gradient relative to the magnetic field strength (as noted above) and therefore is highly efficient in exerting corrective pressure on the plasma; but, since the magnetic field is constant over time, there is far less tendency to produce arcing, and therefore a somewhat stronger magnetic field may be employed for even greater corrective capacity when required. As will be described later in this specification, this feature can be quite helpful at higher chamber pressures.

FIG. 1A illustrates a capacitively coupled plasma reactor capable of providing an adjustable cusp-shaped magnetic field. The reactor of FIG. 1A includes a cylindrical side wall 5, a ceiling 10 that is a gas distribution plate, and a wafer support pedestal 15 that holds a semiconductor workpiece 20. The ceiling 10 or gas distribution plate may be conductive so as to enable it to serve as an anode or it may have an anode attached to it. The ceiling 10 or gas distribution plate is typically made of aluminum and has an internal gas manifold and gas injection orifices in its interior surface that face into the chamber. A process gas supply 25 furnishes process gas to the gas distribution plate 10. A vacuum pump 30 controls the pressure inside the reactor chamber. Plasma source power for igniting and maintaining a plasma inside the reactor chamber is produced by an RF generator 40 connected through an impedance match circuit 45 to the wafer support pedestal 15 so that the wafer support pedestal serves as an RF electrode. The anode (which may be the ceiling 10 formed of a conductor material) is connected to RF ground so that it serves as the counter electrode. Such a reactor tends to have a very non-uniform plasma ion density distribution, which is typically center-high.

FIG. 1B illustrates a feature in which the ceiling 10, rather than being connected directly to ground as in FIG. 1A, is connected through an RF impedance match element 11 (shown only schematically) to a VHF signal generator 12 that furnishes the plasma source power. In this case, the RF generator 40 merely controls the RF bias on the semiconductor wafer or workpiece 20. (The RF impedance match element 11 may be a fixed tuning element such as for example a coaxial tuning stub or a strip line circuit.) Such a feature is discussed in greater detail in a later portion of this specification.

In order to control distribution of plasma ion density, a set of inductive coils are provided above the ceiling 10. In the case of FIG. 1A, the set of coils includes an inner coil 60 and an outer coil 65 which are coaxial with the cylindrical chamber and each constitutes single winding of a conductor. While the windings 60, 65 are illustrated in FIG. 1A as being single turns, they may each consist of plural turns arranged vertically, for example as shown in FIG. 1B. Or, as shown in FIG. 1C, the windings 60, 65 may extend both vertically and horizontally. In the case of FIG. 1A, the inner coil 60 is located farther above the ceiling 10 than the outer coil 65. However, in other cases this arrangement may be reversed, or the two coils 60, 65 may be at the same height above the ceiling 10.

In the case of FIGS. 1A and 1B, a controller 90 determines the magnitude and polarity of currents flowing to the respective overhead coils 60, 65 by controlling respective independent D.C. current supplies 70, 75 that are connected to respective ones of the coils 60, 65. Referring now to FIG. 2, a case is illustrated in which the controller 90 governs the D.C. currents to the coils 60, 65 from a D.C. current supply 76 that furnished current through the controller 90, the controller 90 being connected to respective ones of the coils 60, 65. In either case, the controller 90 is capable of causing D.C. currents of different polarities and magnitudes to flow in different ones of the coils 60, 65. In the case of FIG. 2, the controller 90 includes a pair of potentiometers 82a, 82b that adjust the D.C. current applied to the respective coils 60, 65 and a pair of ganged switches 84a, 84b that independently determine the polarity of the D.C. current applied to each of the coils 60, 65. A programmable device such as a microprocessor 91 can be included in the controller 90 in order to intelligently govern the potentiometers 82a, 82b and the ganged switches 84a, 84b.

The arrangement of the two coils 60, 65 illustrated in FIGS. 1A, 1B and 1C, in which the inner coil 60 is placed at a greater height above the ceiling 10 than the outer coil 65, provides certain advantages. Specifically, the radial component of the magnetic field gradient provided by either coil is, at least roughly, proportional to the radius of the coil and inversely proportional to the axial displacement from the coil. Thus, the inner and outer coils 60, 65 will perform different roles because of their different sizes and displacements: The outer coil 65 will dominate across the entire surface of the wafer 20 because of its greater radius and closer proximity to the wafer 20, while the inner coil 60 will have its greatest effect near the wafer center and can be regarded as a trim coil for finer adjustments or sculpting of the magnetic field. Other arrangements may be possible for realizing such differential control by different coils which are of different radii and placed at different displacements from the plasma. As will be described later in this specification with reference to certain working examples, different changes to the ambient plasma ion density distribution are obtained by selecting not only different magnitudes of the currents flowing in the respective overhead coils (60, 65) but also by selecting different polarities or directions of current flow for the different overhead coils.

FIG. 3A illustrates the radial (solid line) and azimuthal (dashed line) components of the magnetic field produced by the inner coil 60 as a function of radial position on the wafer 20, in the case of FIG. 1A. FIG. 3B illustrates the radial (solid line) and azimuthal (dashed line) components of the magnetic field produced by the outer coil 65 as a function of radial position on the wafer 20. The data illustrated in FIGS. 3A and 3B were obtained in an implementation in which the wafer 20 was 300 mm in diameter, the inner coil 60 was 12 inches in diameter and placed about 10 inches above the plasma, and the outer coil 65 was 22 inches in diameter and placed about 6 inches above the plasma. FIG. 3C is a simplified diagram of the half-cusp shaped magnetic field line pattern produced by the inner and outer overhead coils 60, 65.

The controller 90 of FIG. 2 can change the currents applied to the respective coils 60, 65 in order to adjust the magnetic field at the wafer surface and thereby change the spatial distribution of plasma ion density. What will now be illustrated are the effects of different magnetic fields applied by different ones of the coils 60, 65, in order to illustrate how profoundly the controller 90 can affect and improve plasma ion distribution in the chamber by changing these magnetic

fields. In the following examples, the spatial distribution of the etch rate across the wafer surface rather than the plasma ion distribution is measured directly. The etch rate distribution changes directly with changes in the plasma ion distribution and therefore changes in one are reflected by changes in the other.

FIGS. 4A, 4B, 4C and 4D illustrate the beneficial effects realized using the inner coil **60** only at a low chamber pressure (30 mT). FIG. 4A illustrates measured etch rate (vertical Z axis) as a function of location (horizontal X and Y axes) on the surface of the wafer **20**. FIG. 4A thus illustrates the spatial distribution of the etch rate in the plane of the wafer surface. The center-high non-uniformity of the etch rate distribution is clearly seen in FIG. 4A. FIG. 4A corresponds to the case in which no magnetic field is applied, and therefore illustrates a non-uniform etch rate distribution that is inherent in the reactor and needs correction. The etch rate has a standard deviation of 5.7% in this case. In FIGS. 4 and 5, the magnetic field strength will be described as the axial field near the center of the wafer although it is to be understood that the radial field is the one that works on the radial distribution of plasma ion density to improve uniformity. The axial field is chosen in this description because it is more readily measured. The radial field at the edge of the wafer typically is about one third the axial field at this location.

FIG. 4B illustrates how the etch rate distribution changes when the inner coil **60** has been energized to generate a magnetic field of 9 Gauss. The non-uniformity decreases to a standard deviation of 4.7%.

In FIG. 4C the magnetic field of the inner coil **60** has been increased to 18 Gauss, and it can be seen that the peak at the center has been greatly diminished, with the result that the etch rate standard deviation across the wafer is reduced to 2.1%.

In FIG. 4D the magnetic field of the inner coil **60** has been further increased to 27 Gauss, so that the center high pattern of FIG. 4A has been nearly inverted to a center low pattern. The standard deviation of the etch rate across the wafer surface in the case of FIG. 4D was 5.0%.

FIGS. 5A, 5B, 5C and 5D illustrate the beneficial effects of using both the coils **60**, **65** at higher chamber pressures (200 mT). FIG. 5A corresponds to FIG. 4A and depicts the center-high etch rate non-uniformity of the reactor uncorrected by a magnetic field. In this case, the standard deviation of the etch rate across the wafer surface was 5.2%.

In FIG. 5B, the outer coil **65** has been energized to produce a 22 Gauss magnetic field, which decreases somewhat the center peak in the etch rate distribution. In this case, the etch rate standard deviation has been decreased to 3.5%.

In FIG. 5C, both coils **60**, **65** are energized to produce a 24 Gauss magnetic field. The result seen in FIG. 5C is that the center peak in the etch rate distribution has been significantly decreased, while the etch rate near the periphery has increased. The overall effect is a more uniform etch rate distribution with a low standard deviation of 3.2%.

In FIG. 5D, both coils are energized to produce a 40 Gauss magnetic field, producing an over-correction, so that the etch rate distribution across the wafer surface has been transformed to a center-low distribution. The etch rate standard deviation in this latter case has risen slightly (relative to the case of FIG. 5C) to 3.5%.

Comparing the results obtained in the low pressure tests of FIGS. 4A–4D with the high pressure tests of FIGS. 5A–5D, it is seen that the higher chamber pressure requires a much greater magnetic field to achieve a similar correction

to etch rate non-uniform distribution. For example, at 30 mT an optimum correction was obtained using only the inner coil **60** at 18 Gauss, whereas at 300 mT a magnetic field of 24 Gauss using both coils **60**, **65** was required to achieve an optimum correction.

FIG. 6 shows that the magnetic fields of the overhead coils greatly affect the uniformity of plasma ion density or etch rate distribution, but do not greatly affect etch rate itself. This is an advantage because, while it is desirable to improve uniformity of etch rate distribution, it is preferable to not change the etch rate chosen for a particular semiconductor process. In FIG. 6, the diamond symbols depict measured etch rate (left-hand vertical axis) as a function of magnetic field (horizontal axis), while the square symbols depict standard deviation (non-uniformity) of the etch rate (right-hand vertical scale) as a function of the magnetic field. The change in non-uniformity over the illustrated range is about one order of magnitude, the change in etch rate is only about 25%.

The overhead coil inductors **60**, **65** of FIGS. 1A, 1B and 1C may be used with a conventional MERIE reactor. FIGS. 7 and 8 illustrate an case corresponding to FIG. 1A with the additional feature of four conventional MERIE electromagnets **92**, **94**, **96**, **98** and an MERIE current controller **99**. The current controller **99** provides A.C. currents to the respective MERIE electromagnets **92**, **94**, **96**, **98**. The respective currents are of the same low frequency but have their phases offset by 90 degrees so as to produce a slowly rotating magnetic field within the chamber in the conventional way.

Controlling Plasma Distribution with the Overhead Coils

In accordance with a method of the invention, plasma ion density distribution across the wafer surface that is inherent in a particular reactor is tailored in a particular way by selecting a particular the magnetic field produced by the overhead coils **60**, **65**. For example, the plasma distribution may be tailored to produce a more uniform etch rate distribution across the wafer surface. This tailoring is accomplished, for example, by programming the controller **90** to select optimum polarities and amplitudes of the D.C. current flow in the overhead coils. While the present example concerns a reactor with only two concentric overhead coils (i.e., the coils **60** and **65**), the method can be carried out with more than two coils, and may provide more accurate results with a greater number of overhead coils. The magnetic field is tailored by the controller **90** to change the plasma ion density distribution across the wafer surface, which in turn affects the etch rate distribution.

A first step is to measure the etch rate distribution across the wafer surface in the absence of any corrective magnetic field from the overhead coils **60**, **65**. A next step is to determine a change in the plasma ion density distribution that renders the etch rate distribution more uniform. A final step is to determine a magnetic field that would produce the desired change in plasma ion density distribution. Given this magnetic field, the magnitudes and directions of the currents in the overhead coils **60**, **65** necessary to produce such a field can be computed from well-known static magnetic field equations.

We have found a way of computing, from the magnetic field, pressure exerted by the magnetic field of the overhead coils **60**, **65** on the plasma (the so-called “magnetic pressure”). This will be discussed below. The magnetic pressure on the plasma produces a change in plasma ion density distribution. This change in plasma ion density distribution produces a proportional change in etch rate distribution across the wafer surface, which can be directly observed. The plasma ion density distribution across the

wafer surface and the etch rate distribution are therefore at least roughly related by a factor of proportionality.

Initially, the spatial distribution of the etch rate across the wafer surface is measured prior to the application of magnetic fields from the overhead coils **60**, **65**. From this, a desired change in etch rate distribution (to achieve a uniform distribution) can be determined. Next, the spatial distribution of the magnetic field produced by each overhead coil **60**, **65** as a function of location within the chamber and current flow in the coil is determined analytically from the geometry of each coil. Then, by applying a known set of currents to the coils and then measuring the resulting change in etch rate distribution across the wafer surface, a linear scale factor can be deduced that relates the vector sum of the magnetic fields from all the coils at the wafer surface to the change in etch rate distribution at the wafer surface. (This scale factor is generally a function of neutral pressure in the plasma and is operative up to about 500 mT chamber pressure.) Therefore, given a desired change or correction in etch rate distribution (to achieve better uniformity), the necessary magnetic fields can be found (in a manner described later in this specification), and the corresponding coil currents can be inferred therefrom using the magnetic field spatial distribution function previously determined analytically.

The desired correction to the non-uniformity in etch rate distribution can be established in a variety of ways. For example, the 2-dimensional etch rate distribution across the wafer surface can be subtracted from a uniform or average etch rate to produce a "difference" distribution. The non-uniformities in etch rate distribution to be corrected in this method are the result of various factors in the reactor chamber, including non-uniform application of the capacitively coupled source power, non-uniform process gas distribution as well as non-uniform plasma ion density distribution. In the foregoing method, the non-uniformities are corrected by changing the plasma ion density distribution by magnetic pressure.

The following method can also be employed to establish a "corrected" plasma distribution that is non-uniform in some desired way. In this case, the correction to be made is the difference between the "uncorrected" or ambient plasma ion density distribution and the desired distribution (that is itself non-uniform). Thus, the method is useful for making the plasma density distribution either more uniform or of a particular selected density distribution pattern that is not necessarily uniform.

A series of steps for carrying out the foregoing method will now be described with reference to FIG. 9.

The first step (block **910** of FIG. 9) is to analytically determine, for each one of the overhead coils **60**, **65**, the expression for the magnetic field at the wafer surface as a function of current flow in the coil and radial location on the wafer surface. Using cylindrical coordinates, this expression may be written, for the  $i^{th}$  coil, as  $B_i(r, z=wafer, I_i)$ . It is determined from the Biot-Savart law in a very straightforward manner.

The next step (block **920** of FIG. 9) is carried out with no current flowing in the overhead coils **60**, **65**. In this step, the spatial distribution of plasma ion density across the wafer surface is measured. This spatial distribution may be written as  $n(r, z=wafer)$ . In this step, the plasma ion density distribution can be measured indirectly by measuring the etch rate distribution across the surface of a test wafer. The skilled worker can readily infer the plasma ion density distribution from the etch rate distribution.

Next, in the step of block **930**, a correction,  $c(r)$ , to the measured plasma ion density spatial distribution function

$n(r, z=wafer)$  measured in the previous step is determined. The correction  $c(r)$  may be defined in any number of appropriate ways. For example, it may be defined as the maximum value  $n(r, z=wafer)_{max}$  minus  $n(r, z=wafer)$ . In this way, adding  $c(r)$  to  $n(r, z=wafer)$  produces a "corrected" distribution with a uniform amplitude equal to  $n(r)_{max}$ . Of course, the correction function  $c(r)$  may be defined differently to produce a different uniform amplitude. Or, as briefly noted above, if the desired distribution is non-uniform, then the correction is the difference between the desired distribution and  $n(r, z=wafer)$ .

The next step (block **940**) is to select a "test" current  $I_i$  for each of the overhead coils **60**, **65** and apply that current to the appropriate coil and measure the resulting plasma ion distribution, which may be written  $n(r, z=wafer)_{test}$ . The change in ion distribution  $\Delta n(r)$  is obtained by subtracting the ion distributions measured with and without the magnetic field:

$$\Delta n(r) \approx n(r, z=wafer) - n(r, z=wafer)_{test}$$

The next step (block **950**) is to compute a scale factor  $S$  relating the pressure gradient exerted by the magnetic field (i.e., the magnetic pressure) to the change in ion distribution  $\Delta n(r)$ . This computation is performed by dividing the magnetic pressure gradient by  $\Delta n(r)$ . The magnetic pressure gradient of the magnetic field  $B(r, z=wafer, I_i)$  of the  $i^{th}$  coil is computed individually for each of the coils in accordance with the magneto-hydrodynamics equation:

$$\nabla_r P \approx -\nabla_r [B(r, z=wafer, I_i)^2 / 2\mu_0]$$

where the subscript  $r$  denotes radial component. The results thus obtained for each coil individually are then summed together. Therefore, the total magnetic pressure gradient is:

$$-\nabla_r \left\{ \sum_i [B(r, z = wafer, I_i)^2 / 2\mu_0] \right\}$$

Therefore, the scale factor  $S$  is:

$$S = \left\{ -\nabla_r \left\{ \sum_i [B(r, z = wafer, I_i)^2 / 2\mu_0] \right\} \right\} / \Delta n(r)$$

This division operation may be carried out at different values of  $r$  and the results averaged to obtain  $S$  in scalar form. Otherwise, the scale factor  $S$  will be a function of  $r$  and used in the appropriate manner.

The scale factor  $S$  found in the step of block **950** is a link between the coil currents  $I_i$  that determine the magnetic pressure and a resulting change in ion distribution. Specifically, given a set of coil currents  $I_i$ , a corresponding change in ion distribution  $n(r)$  can be computed by multiplying the magnetic pressure determined from the set of  $I_i$  by the scale factor  $S$ :

$$\Delta n(r) = \left\{ -\nabla_r \left\{ \sum_i [B(r, z = wafer, I_i)^2 / 2\mu_0] \right\} \right\} / S$$

This fact provides the basis for the following step (block **960**) in which a computer (such as the microprocessor **91**) uses the foregoing equation to search for a set of coil currents  $I_i$  that produces the best approximation to previously specified or desired change in plasma ion density distribution,  $\Delta n(r)$ . In this case, the desired change is equal

## 11

to the correction function  $c(r)$  computed in the step of block **930**. In other words, the computer searches for a set of coil currents  $I_i$  that satisfies the following condition:

$$\left\{ -\nabla_r \left\{ \sum_i [B(r, z = \text{wafer}, I_i)^2 / 2\mu_0] \right\} \right\} = c(r)S$$

This search may be carried out by well-known optimization techniques involving, for example, the method of steepest descents. Such techniques are readily carried out by the worker skilled in this field and need not be described here.

The magnitudes and polarities of the set of coil currents  $I_i$  discovered by the search are then sent to the controller **90**, which in turn applies these currents to the respective coils **60, 65**.

FIG. **10** compares magnetic pressure (solid line) with the measured change in plasma ion distribution (dotted line) as a function of radial position at the wafer surface. As discussed above, the magnetic pressure is the gradient of the square of the magnetic fields of the overhead coils. FIG. **10** indicates that there is good correlation between magnetic pressure and change in ion density distribution.

The application of such a method is illustrated in FIGS. **11–14**. FIG. **11** illustrates how non-uniformity or the standard deviation (vertical axis) in the etch rate spatial distribution at the wafer surface varied with coil current in one of the overhead coils. At zero coil current, the standard deviation was about 12%, and the ion distribution was center-high as shown in FIG. **12**.

The minimum non-uniformity at about 3% was achieved at a coil current of about 17 amperes. This represents an improvement by about a factor of four (i.e., 12% to 3% standard deviation in the etch rate distribution). The actual or measured etch rate distribution was as shown in FIG. **13A**, while the etch rate distribution predicted using the techniques of FIG. **9** was as shown in FIG. **13B**.

At the high coil current of 35 amperes, the etch rate distribution standard deviation was about 14%. The measured etch rate spatial distribution was as shown in FIG. **14A** while the predicted distribution was as shown in FIG. **14B**.

Referring again to FIG. **13A**, the most uniform ion distribution obtained is certainly not flat and in fact has “bowl” shape, being concave near the periphery and convex near the center. It is possible that with a greater number of independent overhead coils (e.g., three or more), the optimization of currents may be carried out with greater resolution and better uniformity in results. Therefore, the invention is not limited to the cases having only two coils. The invention may be implemented with varying results using less than or more than two overhead coils.

The same method may be applied in order to control plasma ion density distribution or etch rate distribution at the ceiling surface. Such an approach may be useful during chamber cleaning operations, for example. FIG. **15** illustrates a version of the method of FIG. **9** in which uniformity of the spatial distribution of ion density (or, etch rate) is optimized. The steps of FIG. **15**, namely blocks **910'**, **920'**, **930'**, **940'**, **950'** and **960'** are the same as the steps of FIG. **9**, namely blocks **910**, **920**, **930**, **940**, **950** and **960**, except that they are carried out for the ceiling plane rather than the wafer plane:

The first step (block **910'** of FIG. **15**) is to analytically determine, for each one of the overhead coils **60, 65**, the expression for the magnetic field at the ceiling surface as a function of current flow in the coil and radial location on the wafer surface. Using cylindrical coordinates, this expression

## 12

may be written, for the  $i^{\text{th}}$  coil, as  $B_i(r, z=\text{ceiling}, I_i)$ . It is determined from simple static magnetic field equations and is a function not only of coil current  $I_i$  and radial location  $r$  on the ceiling surface but also of certain constants such as the radius of the coil and the distance,  $z=\text{ceiling}$ , between the coil and the ceiling interior surface.

The next step (block **920'** of FIG. **15**) is carried out with no current flowing in the overhead coils **60, 65**. In this step, the spatial distribution of plasma ion density across the ceiling surface is measured. This spatial distribution may be written as  $n(r, z=\text{ceiling})$ . In this step, the plasma ion density distribution can be measured by a conventional probe or other indirect techniques.

Next, in the step of block **930'**, a correction,  $c'(r)$ , to the measured plasma ion density spatial distribution function  $n(r, z=\text{ceiling})$  measured in the previous step is determined. (It should be noted that the prime notation ' is employed here to distinguish the computations of FIG. **15** from those of FIG. **9** described above, and does not connote a derivative as used herein.) The correction  $c'(r)$  may be defined in any number of appropriate ways. For example, it may be defined as the maximum value  $n(r, z=\text{ceiling})_{\text{max}}$  minus  $n(r, z=\text{ceiling})$ . In this way, adding  $c'(r)$  to  $n(r, z=\text{ceiling})$  produces a “corrected” distribution with a uniform amplitude equal to  $n(r)_{\text{max}}$ . Of course, the correction function  $c'(r)$  may be defined differently to produce a different uniform amplitude. Also, if a particular non-uniform distribution is desired, then the correction is the difference between the uncorrected or ambient plasma distribution  $n(r, z=\text{ceiling})$  and the desired non-uniform distribution. Thus, the method can be employed to establish either a desired plasma ion distribution having a particular non-uniform pattern or to establish a uniform plasma ion density distribution.

The next step (block **940'**) is to select a “test” current  $I_i$  for each of the overhead coils **60, 65** and apply that current to the appropriate coil and measure the resulting plasma ion distribution, which may be written  $n(r, z=\text{ceiling})_{\text{test}}$ . The change in ion distribution  $\Delta n(r)$  is obtained by subtracting the ion distributions measured with and without the magnetic field:

$$\Delta n'(r) = n(r, z=\text{ceiling}) - n(r, z=\text{ceiling})_{\text{test}}$$

The next step (block **950'**) is to compute a scale factor  $S'$  relating the pressure gradient exerted by the magnetic field (i.e., the magnetic pressure) to the change in ion distribution  $\Delta n'(r)$ . This computation is performed by dividing the magnetic pressure gradient by  $\Delta n'(r)$ . The magnetic pressure gradient of the magnetic field  $B(r, z=\text{ceiling}, I_i)$  of the  $i^{\text{th}}$  coil is computed individually for each of the coils in accordance with the magneto-hydrodynamics equation:

$$\nabla_r P = -\nabla_r [B(r, z=\text{ceiling}, I_i)^2 / 2\mu_0]$$

where the subscript  $r$  denotes radial component. The results thus obtained for each coil individually are then summed together. Therefore, the total magnetic pressure gradient is:

$$-\nabla_r \left\{ \sum_i [B(r, z = \text{wafer}, I_i)^2 / 2\mu_0] \right\}$$

## 13

Therefore, the scale factor S is:

$$S' = \left\{ -\nabla_r \left\{ \sum_i [B(r, z = \text{wafer}, I_i)^2 / 2\mu_0] \right\} \right\} / \Delta n'(r)$$

The scale factor S' found in the step of block 950' is a link between the coil currents  $I_i$  that determine the magnetic pressure and a resulting change in ion distribution. Specifically, given a set of coil currents  $I_i$ , a corresponding change in ion distribution  $n'(r)$  can be computed by multiplying the magnetic pressure determined from the set of  $I_i$  by the scale factor S':

$$\Delta n'(r) = \left\{ -\nabla_r \left\{ \sum_i [B(r, z = \text{wafer}, I_i)^2 / 2\mu_0] \right\} \right\} / S'$$

This fact provides the basis for the following step (block 960') in which a computer (such as the microprocessor 91) uses the foregoing equation to search for a set of coil currents  $I_i$  that produces the best approximation to previously specified or desired change in plasma ion density distribution,  $\Delta n'(r)$ . In this case, the desired change is equal to the correction function  $c'(r)$  computed in the step of block 930'. In other words, the computer searches for a set of coil currents  $I_i$  that satisfies the following condition:

$$\left\{ -\nabla_r \left\{ \sum_i [B(r, z = \text{wafer}, I_i)^2 / 2\mu_0] \right\} \right\} = c'(r)S'$$

This search may be carried out by well-known optimization techniques involving, for example, the method of steepest descents. Such techniques are readily carried out by the worker skilled in this field and need not be described here.

The magnitudes and polarities of the set of coil currents  $I_i$  discovered by the search are then sent to the controller 90, which in turn applies these currents to the respective coils 60, 65.

With only a single overhead coil, the apparatus can be used to optimize plasma ion distribution uniformity at either the wafer or the ceiling but not both simultaneously. With at least two overhead coils (e.g., the overhead coils 60 and 65), plasma ion distribution uniformity can be at least approximately optimized at both the wafer and the ceiling simultaneously.

#### Steering Plasma with the Overhead Coils

We have discovered that the coil currents  $I_i$  may be selected in such a manner as to steer the plasma toward the ceiling and/or side walls or to steer it to the wafer surface. The coil currents  $I_i$  may also be selected to improve uniformity of plasma density distribution at the ceiling surface in a manner similar to the method of FIG. 9. As a result, the plasma may be concentrated during processing on the wafer, and then during cleaning may be concentrated on the ceiling and/or side walls. By thus concentrating the plasma at the ceiling, cleaning time may be reduced.

In one example, the plasma was steered to the side wall of the chamber by the controller 90 applying a current of -17.5 amperes to the inner coil 60 and a current of +12.5 amperes to the outer coil 65. FIG. 16 illustrates a radial portion of the chamber interior extending along the horizontal axis from zero radius to the periphery of the chamber and extending along the vertical axis from the wafer surface to the ceiling. The small arrows in FIG. 16 indicate the magnitude and direction of the magnetic field at various

## 14

locations in the chamber when the plasma is steered to the side wall of the chamber by the controller 90 applying a current of -17.5 amperes to the inner coil 60 and a current of +12.5 amperes to the outer coil 65. FIG. 17 illustrates the corresponding gradient of the square of the magnetic field at the wafer surface as a function of radial position.

In another example, the plasma was steered to the roof of the chamber by the controller 90 applying a current of -12.5 amperes to the inner coil 60 and a current of +5 amperes to the outer coil 65. FIG. 18 illustrates a radial portion of the chamber interior extending along the horizontal axis from zero radius to the periphery of the chamber and extending along the vertical axis from the wafer surface to the ceiling. The small arrows in FIG. 18 indicate the magnitude and direction of the magnetic field at various locations in the chamber when the plasma is steered to the side wall of the chamber by the controller 90 applying a current of -12.5 amperes to the inner coil 60 and a current of +5 amperes to the outer coil 65. FIG. 19 illustrates the corresponding gradient of the square of the magnetic field at the wafer surface as a function of radial position.

In a further example, plasma was steered along field lines extending from the center of the ceiling to the side wall by the controller 90 applying a current of -25 amperes to the inner coil 60 and a current of +2.75 to the outer coil 65. FIG. 20 illustrates a radial portion of the chamber interior extending along the horizontal axis from zero radius to the periphery of the chamber and extending along the vertical axis from the wafer surface to the ceiling. The small arrows in FIG. 20 indicate the magnitude and direction of the magnetic field at various locations in the chamber when the plasma is steered to the side wall of the chamber by the controller 90 applying a current of -25 amperes to the inner coil 60 and a current of +2.5 amperes to the outer coil 65. FIG. 21 illustrates the corresponding gradient of the square of the magnetic field at the wafer surface as a function of radial position.

FIG. 17 shows that a high positive magnetic pressure on the plasma is exerted near the edge of the chamber when the plasma is steered to the edge. FIG. 19 shows that a low magnetic pressure on the plasma is exerted near the edge of the chamber when the plasma is directed to the edge of the ceiling. FIG. 21 shows that a high negative pressure is present near the chamber edge when the field lines extend from the ceiling to the edge.

Thus, the currents in the overhead coils 60, 65 may be chosen to direct the plasma to various locations in the chamber that may require cleaning, such as the ceiling and the side wall. Or, the plasma may be concentrated more near the wafer. In order to steer the plasma to either the wafer or the ceiling, or to apportion the plasma between the wafer and the ceiling in accordance with some steering ratio SR, a method such as that illustrated in FIG. 22 may be carried out.

Referring now to FIG. 22, the first step (block 2210 of FIG. 22) is to define an analytical model of the magnetic field inside the chamber as a function of all coil currents in the overhead coils (e.g., the pair of coils 60, 65). This is readily accomplished using static magnetic field equations by a worker skilled in this field, and need not be described here. The magnetic field is the sum of the individual magnetic fields from each of the coils. Each individual magnetic field is a function of the diameter of the respective coil, the location of each coil, the current flow in the coil and the location in the chamber. Thus, the magnetic field produced by the  $i^{\text{th}}$  coil may be written as:

$$B(x,y,z,I_i)$$

so that the total magnetic field is:

$$\sum_i \{B(x, y, z, I_i)\}$$

The next step (block **2220**) is to select a set of magnetic fields that fulfill a set of desired process conditions. For example, to steer plasma to the ceiling, a magnetic field is selected that produces a magnetic pressure on the plasma that pushes the plasma toward the ceiling, as illustrated in the example of FIG. **18**. To steer the plasma toward the side wall, a magnetic field is chosen that produces a magnetic pressure on the plasma that pushes the plasma toward the periphery, as illustrated in FIG. **16**.

For each magnetic field defined in the step of block **2220** above that fulfills a particular condition, a computer searches the model defined in the step of block **2210** for a set of coil currents that produce the desired magnetic field. This is the next step of block **2230**. Each set of currents found in the step of block **2230** is stored along with the name of the corresponding condition in a memory location associated with the corresponding process condition (block **2240** of FIG. **22**). Whenever a particular process condition is selected (e.g., steering the plasma to the ceiling), then the microprocessor **91** fetches the set of current values from the corresponding memory location (block **2250**) and causes the corresponding currents to be applied to the appropriate coils (block **2260**).

FIG. **23** shows how the microprocessor **91** may be programmed to respond to user inputs. A determination is first made whether the processing includes etching of the wafer surface (block **2310** and whether the process includes cleaning (etching) the ceiling (block **2320**). If only the wafer is to be etched, then the plasma is steered to the wafer (block **2330**) and the plasma distribution uniformity at the wafer surface is optimized (block **2350**) using the method of FIG. **9**. If the wafer is to be etched while the ceiling is to be cleaned at the same time, then the plasma density is apportioned between the ceiling and the wafer (block **2360**) and plasma density uniformity is optimized at the wafer surface as in FIG. **9** and at the ceiling as in FIG. **15** (block **2370**). If only the ceiling is to be cleaned, then the plasma is steered to the ceiling (block **2380**) and plasma density uniformity at the ceiling is optimized (block **2390**).

Use with VHF Overhead Electrode:

FIG. **24** illustrates how the inner and outer coils **60**, **65** may be combined with a capacitively coupled reactor that has an overhead electrode connected to a VHF plasma source power generator through a fixed tuning stub. Such a reactor is described in U.S. patent application Ser. No. 10/028,922 filed Dec. 19, 2001 by Daniel Hoffman et al. entitled "Plasma Reactor with Overhead RF Electrode Tuned to the Plasma" and assigned to the present assignee, the disclosure of which is incorporated herein by reference.

Referring to FIG. **24**, a plasma reactor includes a reactor chamber **100** with a wafer support **105** at the bottom of the chamber supporting a semiconductor wafer **110**. A process kit may include, in an exemplary implementation, a conductive or semi-conductive ring **115** supported by a dielectric ring **120** on a grounded chamber body **127**. The chamber **100** is bounded at the top by a disc shaped overhead conductive electrode **125** supported at a gap length above the wafer **110** on grounded chamber body **127** by a dielectric seal. In one implementation, the wafer support **105** is movable in the vertical direction so that the gap length may change. In other implementations, the gap length may be a fixed predetermined length. The overhead electrode **125**

may be a metal (e.g., aluminum) which may be covered with a semi-metal material (e.g., Si or SiC) on its interior surface, or it may be itself a semi-metal material. An RF generator **150** applies RF power to the electrode **125**. RF power from the generator **150** is coupled through a coaxial cable **162** matched to the generator **150** and into a coaxial stub **135** connected to the electrode **125**. The stub **135** has a characteristic impedance, has a resonance frequency, and provides an impedance match between the electrode **125** and the coaxial cable **162** or the output of the RF power generator **150**, as will be more fully described below. The chamber body is connected to the RF return (RF ground) of the RF generator **150**. The RF path from the overhead electrode **125** to RF ground is affected by the capacitance of the dielectric seal **120** and by the capacitance of the dielectric seal **130**. The wafer support **105**, the wafer **110** and the process kit conductive or semiconductive ring **115** provide the primary RF return path for RF power applied to the electrode **125**.

As in the case of FIG. **1A**, the inner coil **60** is less than half the diameter of the outer coil **65** and is in a plane farther away from the chamber than the outer coil **65**. The outer coil **65** is located at or close to the plane of the top of the electrode **125**, while the inner coil **60** is located well above the electrode **125**. As in the case of FIG. **1**, the D.C. currents in the coils **60**, **65** are controlled by the plasma steering controller **90** governing the current supplies **70**, **75** of the coils **60**, **65**.

The capacitance of the overhead electrode assembly **126**, including the electrode **125**, the process kit **115**, **120** and the dielectric seal **130** measured with respect to RF return or ground was, in one exemplary case, 180 pico farads. The electrode assembly capacitance is affected by the electrode area, the gap length (distance between wafer support and overhead electrode), and by factors affecting stray capacitances, especially the dielectric values of the seal **130** and of the dielectric ring **120**, which in turn are affected by the dielectric-constants and thicknesses of the materials employed. More generally, the capacitance of the electrode assembly **126** (an unsigned number or scalar) is equal or nearly equal in magnitude to the negative capacitance of the plasma (a complex number) at a particular source power frequency, plasma density and operating pressure, as will be discussed below.

Many of the factors influencing the foregoing relationship are in great part predetermined due to the realities of the plasma process requirements needed to be performed by the reactor, the size of the wafer, and the requirement that the processing be carried out uniformly over the wafer. Thus, the plasma capacitance is a function of the plasma density and the source power frequency, while the electrode capacitance is a function of the wafer support-to-electrode gap (height), electrode diameter, and dielectric values of the insulators of the assembly. Plasma density, operating pressure, gap, and electrode diameter must satisfy the requirements of the plasma process to be performed by the reactor. In particular, the ion density must be within a certain range. For example, silicon and dielectric plasma etch processes generally require the plasma ion density to be within the range of  $10^9$  to  $10^{12}$  ions/cc. The wafer electrode gap provides an optimum plasma ion distribution uniformity for 8 inch wafers, for example, if the gap is about 2 inches. The electrode diameter is preferably at least as great as, if not greater than the diameter of the wafer. Operating pressures similarly have practical ranges for typical etch and other plasma processes.

But it has been found that other factors remain which can be selected to achieve the above preferred relationship, particularly choice of source frequency and choice of

capacitances for the overhead electrode assembly **126**. Within the foregoing dimensional constraints imposed on the electrode and the constraints (e.g., density range) imposed on the plasma, the electrode capacitance can be matched to the magnitude of the negative capacitance of the plasma if the source power frequency is selected to be a VHF frequency, and if the dielectric values of the insulator components of electrode assembly **126** are selected properly. Such selection can achieve a match or near match between source power frequency and plasma-electrode resonance frequency.

Accordingly in one exemplary case, for an 8-inch wafer the overhead electrode diameter is approximately 11 inches, the gap is about 2 inches, the plasma density and operating pressure is typical for etch processes as above-stated, the VHF source power frequency is 210 MHz (although other VHF frequencies could be equally effective), and the source power frequency, the plasma electrode resonance frequency and the stub resonance frequency are all matched or nearly matched.

More particularly, these three frequencies are slightly offset from one another, with the source power frequency being 210 MHz, the electrode-plasma resonant frequency being approximately 200 MHz, and the stub frequency being about 220 MHz, in order to achieve a de-tuning effect which advantageously reduces the system Q. Such a reduction in system Q renders the reactor performance less susceptible to changes in conditions inside the chamber, so that the entire process is much more stable and can be carried out over a far wider process window.

A currently preferred mode has chamber and pedestal diameters suitable for accommodating a 12 inch diameter wafer, a wafer-to-ceiling gap of about 1.25 inch and an VHF source power frequency of 162 MHz (rather than the 210 MHz referred to above).

The coaxial stub **135** is a specially configured design which further contributes to the overall system stability, its wide process window capabilities, as well as many other valuable advantages. It includes an inner cylindrical conductor **140** and an outer concentric cylindrical conductor **145**. An insulator **147** (denoted by cross-hatching in FIG. **24**), having a relative dielectric constant of 1 for example, fills the space between the inner and outer conductors **140**, **145**. The inner and outer conductors **140**, **145** may be formed, for example, of nickel-coated aluminum. In an exemplary case, the outer conductor **145** has a diameter of about 4 inches and the inner conductor **140** has a diameter of about 1.5 inches. The stub characteristic impedance is determined by the radii of the inner and outer conductors **140**, **145** and the dielectric constant of the insulator **147**. The stub **135** of the case described above has a characteristic impedance of 65  $\Omega$ . More generally, the stub characteristic impedance exceeds the source power output impedance by about 20%–40% and preferably by about 30%. The stub **135** has an axial length of about 29 inches (a half wavelength at 220 MHz) in order to have a resonance in the vicinity of 220 MHz to generally match while being slightly offset from the VHF source power frequency of 210 MHz.

A tap **160** is provided at a particular point along the axial length of the stub **135** for applying RF power from the RF generator **150** to the stub **135**, as will be discussed below. The RF power terminal **150b** and the RF return terminal **150a** of the generator **150** are connected at the tap **160** on the stub **135** to the inner and outer coaxial stub conductors **140**, **145**, respectively. These connections are made via a generator-to-stub coaxial cable **162** having a characteristic impedance that matches the output impedance of the gen-

erator **150** (typically, 50  $\Omega$ ) in the well-known manner. A terminating conductor **165** at the far end **135a** of the stub **135** shorts the inner and outer conductors **140**, **145** together, so that the stub **135** is shorted at its far end **135a**. At the near end **135b** (the unshorted end) of the stub **135**, the outer conductor **145** is connected to the chamber body via an annular conductive housing or support **175**, while the inner conductor **140** is connected to the center of electrode **125** via a conductive cylinder or support **176**. A dielectric ring **180** is held between and separates the conductive cylinder **176** and the electrode **125**.

The inner conductor **140** provides a conduit for utilities such as process gases and coolant. The principal advantage of this feature is that, unlike typical plasma reactors, the gas line **170** and the coolant line **173** do not cross large electrical potential differences. They therefore may be constructed of metal, a less expensive and more reliable material for such a purpose. The metallic gas line **170** feeds gas outlets **172** in or adjacent the overhead electrode **125** while the metallic coolant line **173** feeds coolant passages or jackets **174** within the overhead electrode **125**.

An active and resonant impedance transformation is thereby provided by this specially configured stub match between the RF generator **150**, and the overhead electrode assembly **126** and processing plasma load, minimizing reflected power and providing a very wide impedance match space accommodating wide changes in load impedance. Consequently, wide process windows and process flexibility is provided, along with previously unobtainable efficiency in use of power, all while minimizing or avoiding the need for typical impedance match apparatus. As noted above, the stub resonance frequency is also offset from ideal match to further enhance overall system Q, system stability and process windows and multi-process capability.

Matching the Electrode-Plasma Resonance Frequency and the VHF Source Power Frequency

As outlined above, a principal feature is to configure the overhead electrode assembly **126** for resonance with the plasma at the electrode-plasma resonant frequency and for the matching (or the near match of) the source power frequency and the electrode-plasma frequency. The electrode assembly **126** has a predominantly capacitive reactance while the plasma reactance is a complex function of frequency, plasma density and other parameters. (As will be described below in greater detail, a plasma is analyzed in terms of a reactance which is a complex function involving imaginary terms and generally corresponds to a negative capacitance.) The electrode-plasma resonant frequency is determined by the reactances of the electrode assembly **126** and of the plasma (in analogy with the resonant frequency of a capacitor/inductor resonant circuit being determined by the reactances of the capacitor and the inductor). Thus the electrode-plasma resonant frequency may not necessarily be the source power frequency, depending as it does upon the plasma density. The problem, therefore, is to find a source power frequency at which the plasma reactance is such that the electrode-plasma resonant frequency is equal or nearly equal to the source power frequency, given the constraints of practical confinement to a particular range of plasma density and electrode dimensions. The problem is even more difficult, because the plasma density (which affects the plasma reactance) and the electrode dimensions (which affect electrode capacitance) must meet certain process constraints. Specifically, for dielectric and conductor plasma etch processes, the plasma density should be within the range of  $10^9$ – $10^{12}$  ions/cc, which is a constraint on the plasma reactance. Moreover, a more uniform plasma ion

density distribution for processing 8-inch diameter wafers for example, is realized by a wafer-to-electrode gap or height of about 2 inches and an electrode diameter on the order of the wafer diameter, or greater, which is a constraint on the electrode capacitance. On the other hand, a different gap may be utilized for a 12-inch diameter wafer.

Accordingly, by matching (or nearly matching) the electrode capacitance to the magnitude of the negative capacitance of the plasma, the electrode-plasma resonant frequency and the source power frequency are at least nearly matched. For the general conductor and dielectric etch process conditions enumerated above (i.e., plasma density between  $10^9$ – $10^{12}$  ions/cc, a 2-inch gap and an electrode diameter on the order of roughly 11 inches), the match is possible if the source power frequency is a VHF frequency. Other conditions (e.g., different wafer diameters, different plasma densities, etc.) may dictate a different frequency range to realize such a match in carrying out this feature of the reactor. As will be detailed below, under favored plasma processing conditions for processing 8-inch wafers in several principal applications including dielectric and metal plasma etching and chemical vapor deposition, the plasma capacitance in one typical working example having plasma densities as set forth above was between  $-50$  and  $-400$  pico farads. In an exemplary case the capacitance of the overhead electrode assembly **126** was matched to the magnitude of this negative plasma capacitance by using an electrode diameter of 11 inches, a gap length (electrode to pedestal spacing) of approximately 2 inches, choosing a dielectric material for seal **130** having a dielectric constant of 9, and a thickness of the order of one inch, and a dielectric material for the ring **120** having a dielectric constant of 4 and thickness of the order of 10 mm.

The combination of electrode assembly **126** and the plasma resonates at an electrode-plasma resonant frequency that at least nearly matches the source power frequency applied to the electrode **125**, assuming a matching of their capacitances as just described. We have discovered that for favored etch plasma processing recipes, environments and plasmas, this electrode-plasma resonant frequency and the source power frequency can be matched or nearly matched at VHF frequencies; and that it is highly advantageous that such a frequency match or near-match be implemented. In an exemplary case, the electrode-plasma resonance frequency corresponding to the foregoing values of plasma negative capacitance is approximately 200 MHz, as will be detailed below. The source power frequency is 210 MHz, a near-match in which the source power frequency is offset slightly above the electrode-plasma resonance frequency in order to realize other advantages to be discussed below.

The plasma capacitance is a function of among other things, plasma electron density. This is related to plasma ion density, which needs, in order to provide good plasma processing conditions, to be kept in a range generally  $10^9$  to  $10^{12}$  ions/cc. This density, together with the source power frequency and other parameters, determines the plasma negative capacitance, the selection of which is therefore constrained by the need to optimize plasma processing conditions, as will be further detailed below. But the overhead electrode assembly capacitance is affected by many physical factors, e.g. gap length (spacing between electrode **125** and the wafer); the area of electrode **125**; the range of the dielectric loss tangent for the dielectric seal **130**; the choice of dielectric constant of the dielectric seal **130** between electrode **125** and grounded chamber body **127**; the choice of dielectric constant for the process kit dielectric seal **130**; and the thickness of the dielectric seals **130** and

**120** and the thickness and dielectric constant of the ring **180**. This permits some adjustment of the electrode assembly capacitance through choices made among these and other physical factors affecting the overhead electrode capacitance. We have found that the range of this adjustment is sufficient to achieve the necessary degree of matching of the overhead electrode assembly capacitance to the magnitude of the negative plasma capacitance. In particular, the dielectric materials and dimensions for the seal **130** and ring **120** are chosen to provide the desired dielectric constants and resulting dielectric values. Matching the electrode capacitance and the plasma capacitance can then be achieved despite the fact that some of the same physical factors influencing electrode capacitance, particularly gap length, will be dictated or limited by the following practicalities: the need to handle larger diameter wafers; to do so with good uniformity of distribution of plasma ion density over the full diameter of the wafer; and to have good control of ion density vs. ion energy.

Given the foregoing range for the plasma capacitance and the matching overhead electrode capacitance, the electrode-plasma resonance frequency was approximately 200 MHz for a source power frequency of 210 MHz.

A great advantage of choosing the capacitance of the electrode assembly **126** in this manner, and then matching the resultant electrode-plasma resonant frequency and the source power frequency, is that resonance of the electrode and plasma near the source power frequency provides a wider impedance match and wider process window, and consequently much greater immunity to changes in process conditions, and therefore greater performance stability. The entire processing system is rendered less sensitive to variations in operating conditions, e.g., shifts in plasma impedance, and therefore more reliable along with a greater range of process applicability. As will be discussed later in the specification, this advantage is further enhanced by the small offset between the electrode-plasma resonant frequency and the source power frequency.

FIG. **25** illustrate how the inner and outer coils **60**, **65** may be combined with a capacitively coupled reactor that has an overhead electrode connected to a VHF plasma source power generator through a fixed tuning stub, and has MERIE electromagnets around its periphery. Such a reactor is described in U.S. patent application Ser. No. 10/028,922 filed Dec. 19, 2001 by Daniel Hoffman et al. entitled "Plasma Reactor with Overhead RF Electrode Tuned to the Plasma" and assigned to the present assignee, the disclosure of which is incorporated herein by reference.

Referring to FIG. **25**, a VHF capacitively coupled plasma reactor includes the following elements found in the reactor of FIG. **1A**: a reactor chamber **100** with a wafer support **105** at the bottom of the chamber supporting a semiconductor wafer **110**. A process kit in the illustrated case consists of a semi-conductive or conductive ring **115** supported by a dielectric ring **120** on the grounded chamber body **127**. The chamber **100** is bounded at the top by a disc shaped overhead aluminum electrode **125** supported at a predetermined gap length above the wafer **110** on grounded chamber body **127** by a dielectric seal **130**. The overhead electrode **125** also may be a metal (e.g., aluminum) which may be covered with a semi-metal material (e.g., Si or SiC) on its interior surface, or it may be itself a semi-metal material. An RF generator **150** applies RF power to the electrode **125**. RF power from the generator **150** is coupled through a coaxial cable **162** matched to the generator **150** and into a coaxial stub **135** connected to the electrode **125**. The stub **135** has a characteristic impedance, resonance frequency, and provides an

impedance match between the electrode **125** and the coaxial cable **162**/RF power generator **150**, as will be more fully described below. The chamber body is connected to the RF return (RF ground) of the RF generator **150**. The RF path from the overhead electrode **125** to RF ground is affected by the capacitance of the process kit dielectric ring **120** and the dielectric seal **130**. The wafer support **105**, the wafer **110** and the process kit semiconductive (or conductive) ring **115** provide the primary RF return path for RF power applied to the electrode **125**.

As in the case of FIG. 1A, the inner coil **60** is less than half the diameter of the outer coil **65** and is in a plane farther away from the chamber than the outer coil **65**. The outer coil **65** is located at or close to the plane of the top of the electrode **125**, while the inner coil **60** is located well above the electrode **125**. As in the case of FIG. 1, the D.C. currents in the coils **60**, **65** are controlled by the plasma steering controller **90** governing the current supplies **70**, **75** of the coils **60**, **65**.

The improvement in plasma density distribution uniformity is achieved by the introduction of a set of MERIE electromagnets **902** spaced equally about the periphery of the wafer support pedestal and outside of the reactor chamber (like those shown in FIGS. 7 and 8). These MERIE magnets are adapted to produce a magnetic field that slowly rotates about the axis of symmetry of the cylindrical chamber generally across the surface of the wafer support pedestal. In one case this feature is realized by the MERIE magnets **902** having electromagnet windings wound about respective axes tangent to the circumference of the wafer support pedestal. In this case, an MERIE current controller **904** controls the individual current to each MERIE magnet. A circulating magnetic field is generated in the plane of the workpiece support by the controller **904** providing individual AC currents to each of the individual magnet windings of the same frequency but offset in phase by 90 degrees (or by 360 degrees divided by the number of MERIE magnets). In an alternative case, the feature of a rotating magnetic field is realized by a support frame **1020** (dashed line) supporting all of the MERIE magnets that is rotated about the axis of symmetry by a rotor **1025** (dashed line). In this alternative case, the MERIE magnets are permanent magnets.

A second array of MERIE magnets **906** (shown in dashed line) equally spaced about the workpiece or wafer support pedestal but in a higher plane than the first set of MERIE magnets **902** may be provided as well. Both sets of magnets lie in respective planes that are near the plane of the workpiece support.

The controller **910** applies a low frequency (0.5–10 Hz) AC current to each of the electromagnets **902**, **906**, the phases of the currents applied to neighboring magnets being offset as described above by 90 degrees. The result is a magnetic field that rotates about the axis of symmetry of the workpiece support at the low frequency of the AC current. The magnetic field causes the plasma to be drawn toward the magnetic field near the workpiece surface and to circulate with the field. This stirs the plasma so that its density distribution becomes more uniform. As a result, reactor performance is significantly improved because more uniform etch results are obtained across the entire surface of the wafer.

Combination Overhead Electrode and Gas Distribution Plate:

It is desirable to feed the process gas from the overhead ceiling to improve uniformity of gas distribution within the chamber. For this purpose, the overhead electrode **125** in the

cases of FIGS. 24 and 25 can be a gas distribution showerhead, and therefore has a large number of gas injection ports or small holes **300** in its bottom surface facing the workpiece support **105**. In an exemplary case, the holes **300** were between 0.01 and 0.03 inch in diameter and their centers were uniformly spaced apart by about  $\frac{3}{8}$  inch.

The overhead electrode/gas distribution plate **125** (hereinafter referred to as the gas distribution plate **125**) has improved resistance to arcing. This is due to the introduction of an arc suppression feature that excludes process gas and/or plasma from the center of each opening or hole **300**. This arc suppressing feature is a set of center pieces or disks **302** in the centers of the holes **300** supported at the ends of respective cylindrical fingers or thin rods **303** as shown in the cross-sectional view of FIG. 26 and the enlarged cross-sectional view of FIG. 27. Arcing within a typical gas distribution plate tends to occur near the center of the gas injection holes. Therefore, placing the center pieces **302** at the center of each hole **300** prevents process gas from reaching the center of each hole **300** and therefore reduces the occurrence of arcing. As shown in the plan view of FIG. 28, introduction of the center pieces **302** in the holes **300** transforms the otherwise circular openings or holes **300** into annular openings.

Referring to FIG. 29A, the gas distribution plate **125** with improved arc suppression constitutes a cover **1402** and a base **1404**. The base **1404** is a discoid plate **1406** with the gas injection openings formed therethrough surrounded by an annular wall **1408** having an interior shoulder **1410**. The cover **1402** is also a discoid plate. The disks **302** are the end sections of the cylindrical fingers **303** attached to and extending downwardly from the bottom surface of the cover **1402**. The outer edge of the cover **1402** rests on the shoulder **1410** of the base **1404** to form a gas manifold **1414** (FIG. 26) between the cover **1402** and the base **1404**. Process gas flows into the manifold **1414** from a gas inlet **1416** in the center of the cover **1402**.

The portions of the gas distribution plate **125** that contact process gas or plasma in the chamber can be formed of a metal such as aluminum coated with a semiconductor processing compatible material such as silicon carbide. In this example, all surfaces of the gas distribution plate, with the exception of the top surface of the cover **1402**, are covered with a silicon carbide coating **1502** as indicated in the enlarged partial cross-sectional view of FIG. 29B. As shown in FIG. 30, the aluminum top surface of the cover **1402** is in contact with a temperature-controlled member **1520** that may be water-cooled by water jackets **1522** with coolant circulated by a heat exchanger **1524**, so that the thermally conductive aluminum material of the gas distribution plate **125** has a controlled temperature. Alternatively, as shown in FIG. 31, the water jackets may be within the gas distribution plate **125**.

However, in order for the silicon carbide coating **1502** to have the same controlled temperature, there must be a thermally conductive bond between the silicon carbide coating and the aluminum. Otherwise, the temperature of the silicon carbide coating could fluctuate uncontrollably. In order to achieve good thermal conductivity between the aluminum material of the gas distribution plate **125** and the silicon carbide coating, a polymer bonding layer **1504** is formed between the aluminum gas distribution plate and the silicon carbide coating **1502**, as shown in FIG. 29A. FIG. 29A shows that the polymer bonding layer **1504** is between the silicon carbide coating **1502** and the aluminum base **1404**. The polymer bonding layer provides good thermal conductivity between the aluminum and the silicon carbide

coating **1502**, so that the temperature of the coating **1502** is controlled by the heat exchanger **1524**.

FIGS. **32**, **33** and **34** illustrate how the gas distribution plate **125** of FIG. **29A** can be modified to provide dual zone gas flow control. Such a feature can be employed to help correct an etch rate or deposition rate spatial distribution that is either center high or center low by selecting a process gas distribution that is complementary. Specifically, an annular partition or wall **1602** divides the gas manifold **1414** into a center manifold **1414a** and an outer manifold **1414b**. In addition to the center gas feed **1416** that feeds the center manifold **1414a**, another gas feed **1418** between the center and periphery of the gas distribution plate **125** feeds the outer manifold **1414b**. A dual zone controller **1610** apportions gas flow from a process gas supply **1612** between the inner and outer gas feeds **1416**, **1418**. FIG. **35** illustrates one implementation of the valve **1610** in which an articulating vane **1618** controls the relative amount of gas flow to the inner and outer manifolds **1414a**, **1414b** of the gas distribution plate. An intelligent flow controller **1640** governs the position of the vane **1618**. In another implementation illustrated in FIG. **36**, a pair of valves **1651**, **1652** perform individual gas flow control for respective radial zones of the chamber.

FIG. **37** illustrates an case in which the gas distribution plate **125** has three gas flow zones, the manifold **1414** being separated by inner and outer annular partitions **1604**, **1606** into three manifolds **1414a**, **1414b** and **1414c**. Three respective gas feeds **1416**, **1418**, **1420** provide gas flow to the respective manifolds **1414a**, **b**, **c**.

While various cases have been described above in this specification as having a pair of overhead coils **60**, **65**, FIG. **37** shows that there can be more than two overhead coils. In fact, the case of FIG. **37** is illustrated as having three concentric overhead coils or coils **60**, **64** and **65**. By increasing the number of independently controlled overhead coils, it is felt the resolution with which processing non-uniformities are corrected is increased.

The multiple zone gas distribution plates of FIGS. **34** and **37** enjoy the advantage of flexible control over gas apportionment between inner and outer processing zones of the workpiece. However, another way of customizing gas flow is to do so permanently by providing different gas injection hole sizes at different radii of the gas distribution plate **125**. For example, if the reactor tends to exhibit a spatial etch rate distribution that is center high, then less gas would be supplied near the center and more at the periphery of the chamber by using smaller gas injection holes **300** at the center and larger ones near the periphery. Such a gas distribution plate is illustrated in plan view in FIG. **38**. For a center low etch distribution, the opposite hole arrangement would be employed as illustrated in FIG. **39**.

#### Plasma Steering in the Reactor of FIG. **9**

Plasma steering as described above with reference to FIGS. **11–14** was performed in the case of FIG. **9**. A magnetic field pointing to the side wall was produced by applying a current of  $-13$  amperes to the inner coil **60** and a current of  $+1.4$  amperes to the outer coil **65**. A magnetic field pointing toward the periphery of the ceiling or electrode **125** was produced by applying a current of  $-13$  amperes to the inner coil **60** and a current of  $+5.2$  amperes to the outer coil **65**. A dense magnetic field at the side wall was produced by applying a current of  $-13$  amperes to the inner coil **60** and a current of  $+9.2$  amperes to the outer coil **65**. We found that the etch rate of chamber surfaces during cleaning were improved by as much as 40% by applying a magnetic field pointing toward the periphery of the ceiling or electrode **125** in the manner described above.

#### Coil Configurations

While the foregoing cases have been described with reference to the inner and outer coils **60**, **65**, a greater number of coils may be employed. For example, the case of FIG. **40** has five overhead coils **4060**, **4062**, **4064**, **4066**, **4068**, each with its own current separately controlled by the controller **90**. The coils **4060**, **4062**, **4064**, **4066**, **4068** may be at the same height above the ceiling **125** (as in FIG. **40**) or at different heights. FIG. **41** illustrates an case in which the overhead coils **60**, **65** are at the same height. In FIG. **41**, the windings in each coil **60**, **65** are stacked in both vertical and radial directions. FIGS. **42** and **43** illustrate different cases in which the coils **60**, **65** have windings extending in the vertical direction and in the radial direction.

As discussed previously in this specification with reference to FIG. **1A**, magnetic pressure on the plasma for correcting non-uniform distribution is proportional to the radial component of the gradient of the square of the magnetic field. Thus, the most efficient approach is to employ a magnetic field having a large radial gradient, such as a cusp-shaped magnetic field. As further discussed above, the greater efficiency of the cusp-shaped magnetic field reduces the required strength of the magnetic field for a given amount of magnetic pressure, thereby reducing or eliminating device damage associated with high magnetic fields. FIG. **44** illustrates an case in which a fully cusp-shaped magnetic field is produced by a pair of coils **4420**, **4440** located above and below the chamber, respectively. Current flow in the top and bottom coils **4420**, **4440** is clockwise and counter-clockwise, respectively. FIG. **45** is a simplified illustration of the magnetic field line pattern of the fully cusp-shaped magnetic field produced by the pair of coils **4420**, **4440**.

FIG. **46** illustrates an case in which the four electromagnets **4610**, **4620**, **4630**, **4640** of a conventional MERIE reactor **4650** are employed to generate the fully cusp-shaped magnetic field of FIG. **45**. A current controller **4660** controlling the currents in each of the electromagnets **4610**, **4620**, **4630**, **4640** is programmed to apply D.C. currents flowing in the same (e.g., clockwise) direction in all the electromagnets **4610**, **4620**, **4630**, **4640**, as indicated by the arrows in FIG. **46**. In this way the D.C. currents in the top conductors **4610a**, **4620a**, **4630a**, **4640a** form a clockwise current loop, the D.C. currents in the bottom conductors **4610b**, **4620b**, **4630b**, **4640b** form a counter-clockwise current loop, while at each corner of the array the currents in the vertical conductors of adjacent electromagnets (e.g., the pair of vertical conductors **4620c** and **4630d**) cancel the magnetic fields of one another at the wafer surface. The net effect is to produce clockwise and counter-clockwise current loops at the top and bottom of the chamber, respectively, analogous to the case of FIG. **44**, with the same resulting fully cusp-shaped magnetic field illustrated in FIG. **45**. The reactor of FIG. **46** is operated in any one of three modes:

- (1) magnetic pressure mode, in which the cusp-shaped field is produced;
- (2) sine wave mode, in which four sine wave currents are applied in quadrature to the four electromagnets **4610**, **4620**, **4630**, **4640** to produce a slowly rotating magnetic field over the wafer surface;
- (3) configurable magnetic field (CMF) mode, in which the four electromagnets **4610**, **4620**, **4630**, **4640** are grouped into opposing sets of adjacent pairs, one pair having one D.C. current and the opposite pair having the opposite D.C. current, to produce generally straight magnetic field lines extending across the wafer surface in a diagonal direction relative to the orientation of the

four electromagnets **4610**, **4620**, **4630**, **4640**. This grouping is rotated by switching the currents so that the magnetic field rotates through four diagonal orientations. A time sequence of these orientations are illustrated in FIGS. **47A**, **47B**, **47C** and **47D**.

In FIG. **47A**, the electromagnets **4610**, **4620** have a positive D.C. current flow while the electromagnets **4630**, **4640** have negative D.C. current flow, and the resulting average magnetic field direction is generally from the upper left corner to the lower right corner of the drawing. In FIG. **47B**, the groupings have been switched so that the electromagnets **4620**, **4630** have the positive current flow while the electromagnets **4640**, **4610** have the negative current flow, and the average magnetic field has rotated clockwise by 90 degrees. FIGS. **47C** and **47D** complete the cycle. The strength of the magnetic field lines is determined by the magnitude difference in the positive and negative D.C. currents thus applied, and may be adjusted by programming the controller **4650** as desired.

The method of FIG. **9** may be employed in the CMF mode to accurately select the D.C. currents of the four electromagnets **4610**, **4620**, **4630**, **4640** to produce the best correction for non-uniform etch rate or plasma ion density distribution. In applying the method of FIG. **9** to the CMF mode of FIGS. **47A-D**, the coils of each of the electromagnets or coils **4610**, **4620**, **4630**, **4640** are substituted for the overhead coils **60**, **65**, and all steps of FIG. **9** are performed in accordance with that substitution. The only difference is that the calculation of the magnetic field from each coil is computed as an average over the four time periods corresponding to FIGS. **47A-D**.

FIG. **48** illustrates a reactor including a special grating **4810** inserted over the pumping annulus. The grating **4810** is formed of a semiconductive material such as silicon carbide or of a conductive material such as aluminum and has openings **4820** for permitting gas to be evacuated from the chamber through the pumping annulus. The special grating **4810** excludes plasma from the pumping annulus, providing needed protection and process control. For this purpose, the distance across the interior of each opening **4820** in the radial plane is no greater than twice the plasma sheath thickness. In this way it very difficult if not impossible for a plasma to penetrate through the grating **4810**. This reduces or eliminates plasma interaction with chamber surfaces within the pumping annulus.

FIGS. **49** and **50** illustrate an integrally formed removable chamber liner **4910** that incorporates the plasma-confining grating **4810** of FIG. **48**. The liner **4910** covers the portions of the chamber that are radially outside of the region underlying the electrode **125** and overlying the wafer **110**. Thus, the liner **4910** includes an upper horizontal section **4920** covering an outer periphery of the chamber ceiling, a vertical section **4930** covering the chamber sidewall and a lower horizontal section **4940** that includes the plasma-confining grating **4810** and covers the pumping annulus as well as an annular surface adjacent the wafer **110**. In one case, each of the sections **4920**, **4930**, **4940** are formed together as a monolithic silicon carbide piece **4950**. The liner **4910** further includes an aluminum base **4960** underlying the lower horizontal section **4940** of the silicon carbide piece **4950** and is bonded thereto. The aluminum base **4960** includes a pair of downwardly extending annular rails **4962**, **4964** that are relatively long and thin and provide good electrical conductivity to grounded structural elements of the chamber below the wafer support pedestal **105**.

The reactor can have temperature control elements **4972**, **4974** in thermal contact with the downwardly extending

annular rails **4962**, **4964** as well as a temperature control element **4976** in thermal contact with the vertical side section **4930**. Each of the thermal control elements **4972**, **4974**, **4976** can include cooling apparatus including coolant passages and heating apparatus including an electric heater. It can be desirable to maintain the liner **4910** at a sufficiently high temperature (e.g., as high as 120 degrees F.) to minimize or prevent deposition of polymer or fluorocarbon compounds on interior surfaces of the liner **4910**.

The liner **4910** enhances process stability because it provides a good ground return path. This is due to the fact that the electric potential is uniform along the interior surface of the silicon carbide piece **4950** (including the interior-facing surfaces of the upper horizontal section **4920**, the vertical section **4930** and the lower horizontal section **4940**). As a result, the liner **4910** provides a uniform RF return path at all of its interior-facing surfaces for power delivered either from the overhead electrode **125** or from the wafer pedestal **105**. One advantage is that as plasma fluctuations move the RF return current distribution to concentrate at different parts of the interior surface of the liner **4910**, the impedance presented to that current remains fairly constant. This feature promotes process stability.

FIG. **51** illustrates a modification of the case of FIG. **7** in which the overhead solenoids **60**, **65** define a square pattern symmetrical with the square pattern of the MERIE magnets **92**, **94**, **96**, **98**, and is particularly suited for uniform processing of a square semiconductor or dielectric workpiece **4910**, such as a photolithographic mask.

FIG. **52** illustrates a version of the reactor of FIG. **24** in which the wafer support pedestal **105** may be moved up and down. In addition to the two overhead coils **60**, **65** for controlling plasma ion radial distribution, there is a bottom coil **5210** below the plane of the wafer support pedestal **105**. In addition, there is an outer coil **5220** at the periphery of the chamber. The outer overhead coil **65** and the bottom coil **5210** can have opposing D.C. currents to form a full cusp magnetic field within the chamber.

While the overhead coils **60**, **65** have been described in combination with reactor having an overhead ceiling that serves as both an overhead source power electrode and as a gas distribution plate, the ceiling may be of the type that is not a gas distribution plate, with process gases being introduced in another conventional fashion (e.g., through the side wall). Moreover, the coils **60**, **65** may be employed in a reactor in which source power is not capacitively coupled by a ceiling electrode. Also, the impedance match element for the overhead electrode has been described as being a fixed element such as a coaxial tuning stub. However, the impedance match element may be any suitable or conventional impedance match device such as a conventional dynamic impedance match circuit.

While the invention has been described in detail by specific reference to preferred cases, it is understood that variations and modifications thereof may be made without departing from the true spirit and scope of the invention.

What is claimed is:

1. A plasma reactor comprising:

- a vacuum enclosure including a side wall and a ceiling defining a vacuum chamber, and a workpiece support within said chamber and facing said ceiling for supporting a planar workpiece, said workpiece support and said ceiling together defining a processing region between said workpiece support and said ceiling;
- process gas inlets for furnishing process gas into said chamber;
- an RF power generator and a plasma source power electrode connected to said RF power generator for

27

capacitively coupling plasma source power into said chamber for maintaining a plasma within said chamber; at least a first overhead solenoidal electromagnet adjacent said ceiling, said overhead solenoidal electromagnet, said ceiling, said sidewall and said workpiece support being located along a common axis of symmetry;

a current source connected to said first solenoidal electromagnet and furnishing a first electric current in said first solenoidal electromagnet whereby to generate within said chamber a magnetic field which is a function of said first electric current, said first electric current having a value such that said magnetic field increases uniformity of plasma ion density radial distribution about said axis of symmetry near a surface of said workpiece support; and

wherein said electric current is a D.C. electric current and said magnetic field is a static magnetic field.

2. The reactor of claim 1 wherein said first solenoidal electromagnet is outside of said chamber and faces an external surface of said ceiling.

3. The reactor of claim 1 wherein said plasma source power electrode comprises one of:

(a) said workpiece support;

(b) said ceiling.

4. A plasma reactor comprising:

a vacuum enclosure including a side wall and a ceiling defining a vacuum chamber, and a workpiece support within said chamber and facing said ceiling for supporting a planar workpiece, said workpiece support and said ceiling together defining a processing region between said workpiece support and said ceiling;

process gas inlets for furnishing process gas into said chamber;

an RF power generator and a plasma source power electrode connected to said RF power generator for capacitively coupling plasma source power into said chamber for maintaining a plasma within said chamber;

at least a first overhead solenoidal electromagnet adjacent said ceiling, said overhead solenoidal electromagnet, said ceiling, said sidewall and said workpiece support being located along a common axis of symmetry;

a current source connected to said first solenoidal electromagnet and furnishing a first electric current in said first solenoidal electromagnet whereby to generate within said chamber a magnetic field which is a function of said first electric current, said first electric current having a value such that said magnetic field increases uniformity of plasma ion density radial distribution about said axis of symmetry near a surface of said workpiece support; and

a second overhead solenoidal electromagnet approximately concentric with said first overhead solenoidal electromagnet and connected to said current source, said current source furnishing a second electric current to said second solenoidal electromagnet to generate magnetic flux in said second solenoidal electromagnetic that contributes to said magnetic field, whereby said magnetic field is determined by both said first and second electric currents in said first and second solenoidal electromagnets, said first and second electric currents having values such that said magnetic field increases said uniformity of plasma ion density radial distribution.

5. The reactor of claim 4 wherein said first and second solenoidal electromagnets are outside of said chamber and face an external surface of said ceiling.

28

6. The reactor of claim 5 wherein:

said first solenoidal electromagnet has a diameter on the order of a diameter of said workpiece support and is at a first axial distance above said workpiece support;

said second solenoidal electromagnet has a diameter less than the diameter of said first solenoidal electromagnet and is at a second axial distance above said workpiece support greater than said first axial distance.

7. The reactor of claim 6 wherein:

said first solenoidal electromagnet produces greater radial magnetic pressure on plasma over a greater radial area near a surface of said workpiece support than said second solenoidal electromagnet;

said second solenoidal electromagnet produces magnetic pressure predominantly over a radial area confined near the center of a surface of said workpiece support.

8. The reactor of claim 7 wherein:

said first and second currents constitute a first set of currents whenever plasma is directed primarily at a wafer on said wafer support;

said first and second currents constitute a second set of currents different from said first set of currents whenever plasma is directed toward said ceiling.

9. The reactor of claim 8 wherein said first and second currents constitute a third set of currents different from said first and second sets of currents whenever plasma is directed toward said side wall.

10. A plasma reactor comprising:

a vacuum enclosure including a side wall and a ceiling defining a vacuum chamber, and a workpiece support within said chamber and facing said ceiling for supporting a planar workpiece, said workpiece support and said ceiling together defining a processing region between said workpiece support and said ceiling;

process gas inlets for furnishing process gas into said chamber;

an RF power generator and an electrode connected to said RF power generator for capacitively coupling plasma source power into said chamber for maintaining a plasma;

a plurality of overhead solenoidal electromagnets adjacent said ceiling for generating a combined magnetic field in said chamber comprising a sum of individual magnetic fields produced by respective ones of said plurality of solenoidal electromagnets, a plurality of electric currents flowing in said solenoidal electromagnets, said combined magnetic field being determined by said plurality of electric currents, wherein said overhead solenoid, said ceiling, said sidewall and said workpiece support are located along a common axis of symmetry;

a current source connected to said plurality of solenoidal electromagnets and furnishing said plurality of electric currents to said solenoidal electromagnets, said electric currents having respective values such that said magnetic field increases uniformity of plasma ion density radial distribution about said axis of symmetry near a surface of said workpiece support;

wherein said plurality of solenoidal electromagnets are concentric and are arranged in order of ascending diameter and descending axial height above said ceiling;

wherein the outermost ones of said electromagnets exert a correspondingly greater radial magnetic pressure on plasma across a greater radial area than the innermost ones of said electromagnets; and

29

wherein the innermost ones of said electromagnets exert radial magnetic pressure on plasma within a region confined near the center of said chamber.

**11.** The reactor of claim **10** wherein:

said plurality of electric currents constitute a first set of currents whenever plasma is directed primarily at a wafer on said wafer support;

said plurality of electric currents constitute a second set of currents different from said first set of currents whenever plasma is directed toward said ceiling.

**12.** The reactor of claim **11** wherein said plurality of electric currents constitute a third set of currents different from said first and second sets of currents whenever plasma is directed toward said side wall.

**13.** The reactor of claim **12** wherein in at least one of said sets of currents, at least one of the currents has a polarity opposite to polarities of others of said currents.

**14.** A plasma reactor comprising:

a vacuum enclosure including a side wall and a ceiling defining a vacuum chamber, and a workpiece support within said chamber and facing said ceiling for supporting a planar workpiece, said workpiece support and said ceiling together defining a processing region between said workpiece support and said ceiling;

process gas inlets for furnishing process gas into said chamber;

an RF power generator and an electrode connected to said RF power generator for capacitively coupling plasma source power into said chamber for maintaining a plasma;

a plurality of overhead solenoidal electromagnets adjacent said ceiling for generating a combined magnetic field in said chamber comprising a sum of individual magnetic fields produced by respective ones of said plurality of solenoidal electromagnets, a plurality of electric currents flowing in said solenoidal electromagnets, said combined magnetic field being determined by said plurality of electric currents, wherein said overhead solenoid, said ceiling, said sidewall and said workpiece support are located along a common axis of symmetry;

a current source connected to said plurality of solenoidal electromagnets and furnishing said plurality of electric currents to said solenoidal electromagnets, said electric currents having respective values such that said magnetic field increases uniformity of plasma ion density radial distribution about said axis of symmetry near a surface of said workpiece support; and

wherein said plurality of electric currents are D.C. electric currents and said combined magnetic field is a static magnetic field.

**15.** The reactor of claim **10** further comprising:

plural solenoidal side magnets having plural axes of symmetry perpendicular to and generally extending from said common axis of symmetry, said plural solenoidal side magnets for generating a rotating magnetic field in said processing region.

**16.** The reactor of claim **15** wherein said plural solenoidal side magnets generally face said side wall while said plural overhead solenoidal magnets face said ceiling.

**17.** The reactor of claim **16** wherein said plural solenoidal side magnets are plural side solenoidal electromagnets, said reactor further comprising a current generator for applying respective low frequency sinusoidal currents of different respective phases to said plural side solenoidal electromagnets whereby to generate said rotating magnetic field.

30

**18.** A plasma reactor comprising:

a vacuum enclosure including a side wall and a ceiling defining a vacuum chamber, and a workpiece support within said chamber and facing said ceiling for supporting a planar workpiece, said workpiece support and said ceiling together defining a processing region between said workpiece support and said ceiling;

process gas inlets for furnishing process gas into said chamber;

an RF power generator and a plasma source power electrode connected to said RF power generator for capacitively coupling plasma source power into said chamber for maintaining a plasma;

a plurality of overhead solenoidal magnets adjacent said ceiling having a combined static magnetic field in said chamber comprising a sum of individual static magnetic fields produced by respective ones of said plurality of solenoidal magnets, wherein said overhead solenoid, said ceiling, said sidewall and said workpiece support are located along a common axis of symmetry; and

wherein said combined magnetic field increases uniformity of plasma ion density radial distribution about said axis of symmetry near a surface of said workpiece support.

**19.** The reactor of claim **18** wherein said plurality of solenoidal magnets are concentric and are arranged in order of ascending diameter and descending axial height above said ceiling.

**20.** The reactor of claim **18** wherein:

the outermost ones of said magnets exert a correspondingly greater radial magnetic pressure on plasma across a greater radial area than the innermost ones of said magnets;

the innermost ones of said magnets exert radial magnetic pressure on plasma within a region confined near the center of said chamber.

**21.** A plasma reactor comprising:

a vacuum enclosure including a side wall and a ceiling defining a vacuum chamber, and a workpiece support within said chamber and facing said ceiling for supporting a planar workpiece, said workpiece support and said ceiling together defining a processing region between said workpiece support and said ceiling;

process gas inlets for furnishing process gas into said chamber;

an RF power generator and a plasma source power electrode connected to said RF power generator for capacitively coupling plasma source power into said chamber for maintaining a plasma within said chamber;

an overhead solenoidal magnet outside of said chamber and facing an external surface of said ceiling, said overhead solenoidal magnet, said ceiling, said sidewall and said workpiece support being located along a common axis of symmetry; and

said overhead solenoidal magnet having a D.C. magnetic field within said chamber that has a sufficient radial component to increase uniformity of plasma ion density radial distribution about said axis of symmetry near a surface of said workpiece support.

**22.** A plasma reactor comprising:

a vacuum enclosure including a side wall and a ceiling defining a vacuum chamber, and a workpiece support within said chamber and facing said ceiling for supporting a planar workpiece, said workpiece support and

## 31

said ceiling together defining a processing region between said workpiece support and said ceiling;

process gas inlets for furnishing process gas into said chamber;

an RF power generator and an electrode connected to said RF power generator for capacitively coupling plasma source power into said chamber for maintaining a plasma;

a plurality of overhead solenoidal electromagnets adjacent said ceiling for generating a combined magnetic field in said chamber comprising a sum of individual magnetic fields produced by respective ones of said plurality of solenoidal electromagnets, a plurality of electric currents flowing in said solenoidal electromagnets, said combined magnetic field being determined by said plurality of electric currents, wherein said overhead solenoid, said ceiling, said sidewall and said workpiece support are located along a common axis of symmetry;

said plurality of solenoidal electromagnets being concentric and being arranged in order of ascending diameter and descending axial height above said ceiling;

a plasma steering controller connected to said plurality of solenoidal electromagnets and furnishing said plurality of electric currents to said solenoidal electromagnets, said plurality of electric currents constituting a first set of currents whenever plasma is directed primarily at a wafer on said wafer support and constituting a second set of currents different from said first set of currents whenever plasma is directed toward said ceiling.

**23.** The reactor of claim **22** wherein:

the outermost ones of said electromagnets exert a correspondingly greater radial magnetic pressure on plasma across a greater radial area than the innermost ones of said electromagnets;

the innermost ones of said electromagnets exert radial magnetic pressure on plasma within a region confined near the center of said chamber.

**24.** The reactor of claim **22** wherein said plurality of electric currents constitute a third set of currents different from said first and second sets of currents whenever plasma is directed toward said side wall.

**25.** The reactor of claim **24** wherein in at least one of said sets of currents, at least one of the currents has a polarity opposite to polarities of others of said currents.

## 32

**26.** The reactor of claim **22** wherein said plurality of electric currents are D.C. electric currents and said combined magnetic field is a static magnetic field.

**27.** The reactor of claim **22** further comprising:

plural solenoidal side magnets having plural axes of symmetry perpendicular to and generally extending from said common axis of symmetry, said plural solenoidal side magnets for generating a rotating magnetic field in said processing region.

**28.** The reactor of claim **27** wherein said plural solenoidal side magnets generally face said side wall while said plural overhead solenoidal magnets face said ceiling.

**29.** The reactor of claim **27** wherein said plural solenoidal side magnets are plural side solenoidal electromagnets, said reactor further comprising a current generator for applying respective low frequency sinusoidal currents of different respective phases to said plural side solenoidal electromagnets whereby to generate said rotating magnetic field.

**30.** A plasma reactor comprising:

a vacuum enclosure including a side wall and a ceiling defining a vacuum chamber, and a workpiece support within said chamber and facing said ceiling for supporting a planar workpiece, said workpiece support and said ceiling together defining a processing region between said workpiece support and said ceiling;

process gas inlets for furnishing process gas into said chamber;

an RF power generator and a plasma source power electrode connected to said RF power generator for capacitively coupling plasma source power into said chamber for maintaining a plasma within said chamber;

a plasma RF bias power generator coupled to said workpiece support, whereby said workpiece support constitutes a bias power electrode;

at least a first overhead solenoidal electromagnet adjacent said ceiling, said overhead solenoidal electromagnet, said ceiling, said sidewall and said workpiece support being located along a common axis of symmetry; and

a current source connected to said first solenoidal electromagnet and furnishing a first electric current in said first solenoidal electromagnet whereby to generate within said chamber a magnetic field which is a function of said first electric current.
