(57) **ABSTRACT**

A method includes isolating carbon atoms as conditioned carbide anions below a surface of a reactant liquid. The conditioned carbide anions are then enabled to escape from the reactant liquid to a collection area where carbon nanostructures may form. A carbon structure produced in this fashion includes at least one layer made up of hexagonally arranged carbon atoms. Each carbon atom has three covalent bonds to adjoining carbon atoms and one unbound pi electron.

REACTANT LIQUID SYSTEM FOR FACILITATING THE PRODUCTION OF CARBON NANOSTRUCTURES

CROSS-REFERENCE TO RELATED APPLICATIONS

This application is a continuation of U.S. patent application Ser. No. 11/173,419, filed Jul. 1, 2005 now abandoned, and entitled "Reactant Liquid System for Facilitating the Production of Carbon Nanostructures," which is a continuation-in-part of U.S. patent application Ser. No. 10/887,695, filed Jul. 9, 2004 now U.S. Pat. No. 7,550,128, and entitled "Method and Apparatus for Producing Carbon Nanostructures," and a continuation-in-part of U.S. patent application Ser. No. 11/025,717, filed Dec. 29, 2004 now U.S. Pat. No. 7,563,426, and entitled "Method and Apparatus for Preparing A Collection Surface for Use in Producing Carbon Nanostructures." The Applicant claims the benefit of each of these applications under 35 U.S.C. §120. The entire content of each of these applications is incorporated herein by this reference.

TECHNICAL FIELD OF THE INVENTION

The present invention relates to methods for manufacturing carbon nanotubes and other carbon nanostructures from a carbon-bearing feedstock. In particular, the invention relates to methods for placing carbon atoms in condition to form impurity-free carbon nanostructures. The invention also includes a particular type of carbon nanostructure.

BACKGROUND OF THE INVENTION

Carbon nanostructures have received a great deal of interest since their discovery. It has been suggested that carbon nanostructures may have important applications in electronics, in materials sciences, and in a number of additional fields. As used in this disclosure, a carbon nanostructure comprises a structure formed from chemically bonded carbon atoms, with or without impurities or intentionally added materials incorporated in the carbon structure or adjacent to the carbon structure. Carbon nanostructures include structures in which carbon atoms are arranged in generally a series of interconnected hexagonal rings formed into a tube or other structure. Carbon nanostructures may be single walled or multiple walled nanotubes, nanofibers, nanorope, or nanowire. Single wall nanotubes include a single layer of the hexagonally arranged carbon atoms, while multiple walled nanotubes are made up of an inner layer of carbon atoms and a series of one or more outer layers of hexagonally arranged carbon atom structures.

Despite the interest in carbon nanostructures and the potentially important uses for such structures, the practical application of carbon nanostructures in products has been slowed by the difficulty in manufacturing such structures. Two general types of processes have been employed to produce or isolate carbon nanostructures. One process type uses a plasma arc between carbon electrodes. U.S. Pat. Nos. 5,482,601 and 5,753,088 describe such carbon plasma arc processes for producing carbon nanotubes. Another process type involves simply isolating naturally formed carbon nanotubes from graphite and soot. Such an isolation process or refinement process for carbon nanotubes is described in U.S. Pat. No. 5,560,898.

The prior processes for producing or isolating carbon nanotubes have been found to produce only small quantities of carbon nanotubes of inconsistent quality. The low quality

2

carbon nanotubes produced or isolated by the prior methods commonly included metal or other atoms incorporated in the carbon structure. These impurities incorporated in the walls of the carbon nanotubes may have a negative impact on the qualities and properties of the nanotube and may render it unsuitable for an intended purpose. In particular, prior carbon nanostructure production techniques include no mechanism for preventing hydrogen atoms and other atoms that may be present in the carbon-bearing feed material from being incorporated into the nanocarbon structure. Also, prior carbon nanostructure production techniques tend to allow carbon from the feed material to become incorporated into the carbon nanostructures in an unpredictable fashion outside of the desired interconnected hexagonal ring structure. This inclusion of amorphous carbon in the resulting carbon nanostructure greatly degrades the properties and usefulness of the resulting carbon nanostructure.

SUMMARY OF THE INVENTION

The present invention provides methods for placing carbon in condition to form high-quality, substantially impurity-free carbon nanostructures. The present invention also encompasses a novel type of carbon nanostructure.

A method according to the present invention includes isolating carbon atoms as conditioned carbide anions below a surface of a reactant liquid. The conditioned carbide anions are then allowed to escape from the reactant liquid to a collection area where carbon nanostructures may form. The isolation of carbon atoms as conditioned carbide anions includes two components. A first component involves separating the carbon atoms from a carbon-bearing feed material that has been introduced into the reactant liquid and preventing the carbon atoms from combining with other materials. The second component of isolating carbon atoms as the desired conditioned carbide anions involves increasing the energy state of the separated and isolated carbon atoms. The desired energy state of carbide anions within the scope of the present claims is at least the SP3 hybrid energy state, in which the carbide anions have absorbed greater than 22 eV (electron volt) of energy from the reactant liquid bath. Thus, a "conditioned carbide anion" within the scope of the present claims refers to a carbide anion at least at the SP3 hybrid energy state.

The isolation of carbon atoms as conditioned carbide anions within the scope of the present invention may be accomplished by chemical reduction, chemical oxidation, reactions from acids, bases, or salts, or pyrolysis in the reactant liquid. For example, one preferred form of the invention utilizes a liquid reactant metal to chemically reduce a carbon-bearing feed material to isolate carbon atoms from the feed material and elevate the energy state of the isolated carbon atoms to form the desired conditioned carbon anions, that is, carbon anions at least at the SP3 hybrid energy state. Regardless of the particular mechanism by which the reactant liquid isolates the carbon atoms, maintaining carbon atoms that have been separated from the feed material below the surface of the reactant liquid allows the carbon atoms to remain isolated from each other and other materials with which bonds could form and allows the carbon atoms to be energized to the desired conditioned state.

A carbon structure according to the present invention includes at least one layer made up of hexagonally arranged carbon atoms. Each carbon atom has three covalent bonds to adjoining carbon atoms and one unbound pi electron. Thus, the carbon structure according to the present invention is a pure carbon structure, free of contaminating amorphous carbon and any other contaminating atoms. The carbon structure

according to the invention is also free of hydrogen that would otherwise form a fourth covalent bond with each carbon atom. This contamination-free and hydrogen-free carbon structure may take the form of flat sheets of material or single or multi-walled tubes.

These and other advantages and features of the invention will be apparent from the following description of the preferred embodiments, considered along with the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a diagrammatic representation of an apparatus embodying the principles of the invention.

FIG. 2 is a diagrammatic end view of an outlet end of the reaction chamber shown in FIG. 1.

FIG. 3 is a diagrammatic representation of an alternate collection chamber according to the present invention.

FIG. 4 is a diagrammatic representation of another alternate collection surface arrangement within the scope of the present invention.

FIG. 5 is a diagrammatic representation of another alternate collection chamber according to the present invention.

FIG. 6 is a diagrammatic representation of a test apparatus that has been used to produce carbon nanostructures according to the present invention.

FIG. 7 is a diagrammatic isometric representation of a single-walled carbon nanostructure according to the present invention.

FIG. 8 is a diagrammatic isometric representation of a double-walled carbon nanostructure according to the present invention.

DESCRIPTION OF PREFERRED EMBODIMENTS

The claims at the end of this application set out novel features which the Applicant believes are characteristic of the invention. The various advantages and features of the invention together with preferred modes of use of the invention will best be understood by reference to the following description of illustrative embodiments read in conjunction with the drawings introduced above.

Referring to the diagrammatic representation of FIG. 1, an apparatus 100 for producing carbon nanostructures according to the present invention includes a reactant liquid vessel 101 for containing a reactant liquid 105 at a reactant liquid level 102. An injection arrangement shown generally at reference numeral 103 allows a stream of feed material to be injected into reactant liquid vessel 101 at an injection point 104 below reactant liquid level 102. Apparatus 100 further includes a collection arrangement shown generally in dashed box 106. The illustrated collection arrangement includes a collection chamber 107 positioned to receive effluent escaping from the reactant liquid in an effluent ejection area shown generally at reference numeral 108. The collection arrangement also includes a collection surface 110 within collection chamber 107, the collection surface residing at a position above the reactant liquid level and adjacent to effluent ejection area 108.

The apparatus shown in FIG. 1 includes a reaction chamber portion formed within vessel 101 below the reactant metal level 102. This reaction chamber is shown generally at reference numeral 112 and is defined by a tunnel structure having an upper wall 114 located below the reactant liquid level 102 in vessel 101. The tunnel structure is best shown in the end view of FIG. 2 and includes side walls 115 in addition to the upper wall 114. Referring again to FIG. 1, the tunnel structure

produces an elongated tunnel below the reactant liquid level 102 in vessel 101. Feed material is injected at a feed end 116 of the tunnel structure and reaction products from the reaction of the feed material in the reactant liquid exits the tunnel structure at an outlet end 117. The figures show these reaction products in the reactant metal as bubbles 118. Preferred forms of the tunnel structure include one or more flow channels or lips 119 at the outlet end 117 that each defines a location in which the relatively light reaction products collected at the top of the tunnel structure exit the tunnel. The importance of directing the reaction products to particular locations will be described further below in connection with the collection chamber 107.

The function of the tunnel structure defined by side walls 115 and upper wall 114 is to help ensure good contact between the reactant liquid and the feed material and between the reactant liquid and any intermediate reaction products that form from initial reactions of feed material, and to ensure sufficient residence time for the feed material and reaction products in the reactant liquid. This contact and residence time helps ensure the isolation of substantially all carbon from the carbon-bearing feed material and elevation of the resulting carbon anions to the desired conditioned carbon anions. The placement of the tunnel below the reactant liquid level 102 also ensures that a pressure is maintained on the feed material and intermediate reaction products. This pressure results from the column of reactant liquid above the feed material and intermediate reaction products. The tunnel structure shown in the present drawings includes one or more vents or passages 120 along the length of the tunnel structure to allow fresh reactant liquid to continually flow into the tunnel structure along its length and to help accommodate the expansion of gasses in the tunnel.

The form of the invention shown in FIG. 1 includes an enclosure 121 over reactant liquid vessel 101. It will be appreciated that apparatus 100 will also commonly require an arrangement for heating the reactant liquid to maintain it in a desired temperature range, and an arrangement for circulating the reactant liquid in vessel 101 and especially through the reaction chamber 112 defined by the tunnel structure walls 114 and 115 in the direction shown by arrow F in FIG. 1. Heating the reactant liquid may be accomplished by burning suitable hydrocarbon fuels, by electrical induction, or by any other suitable process. Further details on the tunnel structure and the structure of vessel 101 and arrangements for heating and circulating reactant liquid, particularly a liquid reactant metal such as aluminum alone or together with other metals, may be found in U.S. Pat. No. 6,227,126, which is incorporated herein by this reference. However, since these details are not necessary for an understanding of the present invention, such details are omitted here.

Feed material injection arrangement 103 includes an injection conduit 124 having an outlet end that extends to injection point 104 below the reactant liquid level 102. The injection point 104 is located so that the feed material exiting the conduit is captured within the tunnel structure under upper wall 114, and thus is forced to flow along the upper wall and along the entire length of the tunnel structure before it can exit the reactant liquid in effluent ejection area 108. This flow along the lower surface of upper tunnel wall 114 helps ensure complete destruction of the feed material and any intermediate reaction products that may form as the feed material is destroyed by reaction with or in the reactant liquid, and results in the formation of the desired isolated carbon anions in the reactant liquid. Injection point 104 is also preferably at a depth below the reactant liquid level 102 to produce a desired reaction pressure due to the column of reactant liquid

5

above the injection point. For a predominantly aluminum reactant liquid, this pressure is approximately 2.4 pounds per square inch above atmospheric pressure. Due to the relatively high temperature that may be present in the reactant liquid, conduit **124** is preferably enclosed in a suitable thermal insulating sheath **127** which may comprise one or more layers of insulating material or a jacket through which a cooling fluid may be circulated. The upper end of conduit **124** is connected to a line which ultimately extends to a feed material supply **128** and preferably a purge gas supply **129** through a suitable arrangement of control valves **130**.

Collection chamber **107** is located with respect to the outlet end **117** of the tunnel structure so that reaction products **118** are ultimately captured in the collection chamber. That is, the reaction products **118** flow up from flow channels **119** and traverse the surface of the reactant liquid in effluent ejection area **108** into the area defined as collection chamber **107**. This area is defined by chamber walls **134**. An outlet conduit **135** receives material that is not collected within chamber **107**, and removes that material from the system. This material removed through conduit **135** may include gasses such as hydrogen and nitrogen, carbon, and particulates that escape the reactant liquid bath. Although it is not shown in FIG. **1**, it will be appreciated that suitable equipment may be connected to outlet conduit **135** to remove recoverable material from the effluent that reaches the outlet conduit.

In the form of the invention shown in FIG. **1**, collection surface **110** comprises an upper surface of a collection structure **138** that either floats or is fixed so that a lower surface **139** of the structure resides below reactant liquid level **102** while the collection surface **110** resides above the reactant liquid level in collection chamber **107**. A deflection surface **140** may also be included in collection chamber **107** positioned to deflect effluent traversing the surface of the reactant liquid in effluent ejection area **108** so that the effluent, including the conditioned carbon atoms, flow over collection surface **110**. It will be noted that in the embodiment shown in FIG. **1**, both collection surface **110** and deflection surface **140** extend in a respective plane transverse to a device vertical axis **V**. Also, in the embodiment shown in FIG. **1**, lower surface **139** of collection structure **138** forms a blocking structure positioned above the respective flow channel **119** and below the reactant liquid level **102** in reactant liquid vessel **101**. The effluent from the feed material/reactant liquid reaction must flow around this blocking structure in order to reach effluent ejection area **108** and exit the reactant liquid.

Collection surface **110** may be located from just above reactant liquid level **102** (an inch or less) to as much as three feet above the reactant liquid. One or more seed objects may be included on collection surface **110**. Seed objects may be any type of objects that encourage or facilitate the assembly of carbon nanostructures from the conditioned carbon atoms exiting the reactant liquid bath. Seed objects may include pure catalyst metals such as titanium and platinum, for example, or metal oxides such as manganese oxide, magnesium oxide, copper oxide, chromium oxide, and titanium oxide, for example. The catalyst may or may not be sacrificial. Seed objects may also include graphite surfaces, carbon surfaces, and seed carbon nanostructures. The seed objects may be spaced apart across collection surface **111** or may make up the entire collection surface. For example, the entire collection structure **138** may be formed from graphite or carbon or some other material that serves as a seed material. In another example, seed objects comprising atoms of catalyst metals may be liberated from reactant liquid **105** and deposited across collection surface **110** as described in related U.S. patent application Ser. No. 11/025,717.

6

Referring to FIG. **3**, an alternate collection surface arrangement includes a collection structure **301** mounted on a rod **302** or other suitable support in collection chamber **303** defined by chamber walls **306**. Lower surface **304** of structure **301** provides a blocking surface similar to surface **139** shown in FIG. **1**, while surface **305** provides the collection surface in the embodiment shown in FIG. **3**. This alternate embodiment is advantageous because the entire collection structure **301** may be readily withdrawn from collection chamber **303** through a suitable access opening (not shown) in the chamber in order to gain access to the collection surface **305** and remove carbon nanostructures that have collected on the collection surface. It is noted that the vessel **101**, outlet conduit **135**, tunnel upper wall **114**, reactant liquid **105** and reactant liquid level **102** are identical to those shown in FIG. **1**.

The alternative embodiment shown in FIG. **4**, includes collection structures **401** similar to structure **301** shown in FIG. **3**. However, the embodiment shown in FIG. **4** also includes additional blocking structures **402** supported below the reactant liquid level **102**. These blocking structures **402** direct reaction products in the reactant liquid **105** toward a central portion of each collection structure **401** so that the reaction products must flow around the collection structures to exit the reactant liquid. It will be noted that the view in FIG. **4** is at about 90 degrees to the view in FIGS. **1** and **3**. It will be further noted that multiple spaced apart flow channels at the outlet end **117** of a tunnel structure such as that shown in FIG. **1** would be required to allow the reaction products to flow up properly beneath each of the blocking structures **402** shown in FIG. **4**.

The alternate collection arrangement shown in FIG. **5** includes a series of collection members **501** having vertically extending collection surfaces **502**. The vertical orientation of surfaces **502** is in contrast to the collection surface **110** shown in FIG. **1**, which extends transverse to the device vertical axis **V**. That is, the collection surfaces **502** extend parallel to device vertical axis **V** rather than transverse. Collection members **501** may comprise cylinders or plates that are spaced apart sufficiently to allow effluent other than the materials to be incorporated in nanostructures to reach outlet conduit **135**.

A method according to the present invention may now be described with reference particularly to the embodiment shown in FIG. **1**. Such a method includes isolating carbon atoms from hydrocarbon molecules by reaction within or with a reactant liquid and maintaining the isolated carbon atoms in the reactant liquid for a sufficient period of time to place the carbon atoms in the desired excited form as conditioned carbon anions. This step is performed in apparatus **100** in FIG. **1** by contacting a carbon-bearing feed material from supply **128** with the reactant liquid in vessel **101**. Sufficient contact time to produce the conditioned carbon anions is achieved in apparatus **100** by ensuring that the feed material and any intermediate reaction products must flow the entire length of the tunnel structure defined by upper tunnel wall **114** and side walls **115**. Also, the reactant liquid is maintained at a suitable reaction temperature to effect the desired liberation of carbon atoms. For example, where the reactant liquid is made up predominantly of aluminum the liquid is maintained between approximately 650 degrees Celsius and approximately 950 degrees Celsius, and more preferably at approximately 900 degrees Celsius. Injection point **104** and upper tunnel wall **114** are located deep enough in the reactant liquid to produce a desired reaction pressure, preferably at least 2.4 psig at least at some point in the apparatus where the reactant liquid comprises predominantly aluminum. These preferred

temperatures and pressure conditions together with the nature of the reactant liquid ensure the production of the desired conditioned carbon anions.

The time and energy required to liberate carbon atoms from the carbon-bearing feed material will depend upon the nature of the feed material. For example, assuming a feed material of CH_3 , approximately 1735.5 Btu of kinetic energy per mole of feed material will be required to liberate the carbon atoms from the CH_3 molecules. The energy required for this carbon liberation step may also be calculated for other carbon-bearing feed materials based on the bond energy required to break the chemical bonds to or between the carbon atoms in the respective feed material. Additional energy is then required to produce the desired conditioned carbon anions, that is, carbon anions at least at the SP3 hybrid energy state. Specifically, about 11 eV of kinetic energy is required to energize the carbon from the ground state to the first activation energy level, and about another 1.88 eV of energy is required to move the carbon (that is, the electrons associated with the carbon atom) from the first activation energy to the second activation energy level, which may be referred to as the 3PS2P2 energy state. From this point, additional energy in the amount of approximately 8 eV is required to move the electrons associated with the carbon atom from the second activation energy level to the 5S atomic structure of the SP3 hybrid energy state. Thus, once the chemical bonds of the feed stock are broken to isolate a carbon atom into the reactant liquid, the carbon then requires about 3.1703×10^{-21} Btus of energy per carbon atom, that is, about 25 electron volts of kinetic energy per atom, to be converted to the desired conditioned carbon anions. It will be noted that these conditioned carbon anions remain highly energetic while in the high energy conditions of the liquid reactant, and remain highly energetic and unstable at the time they escape from the high energy conditions of the liquid reactant material, such as by eluding into the collection chamber **107** shown in FIG. **1**.

To produce carbon nanostructure from the conditioned carbon anions generated in the reactant liquid, the conditioned carbon anions are allowed to traverse the surface of the reactant liquid in effluent ejection area **108**, and are directed across collection surface **110** which may include one or more seed materials or objects. Collection conditions are maintained in chamber **107** and at collection surface **110** at which the conditioned carbon anions phase change to a ground state by carbon nanostructure self-assembly.

Maintaining collection conditions in chamber **107** and at surface **110** may include controlling the temperature and effluent flow conditions as well as the appropriate atmosphere in chamber **107**. In particular, an appropriate collection atmosphere comprises an atmosphere that does not chemically or physically interfere with the desired carbon nanostructure formation. Purging collection chamber **107** of materials that could chemically react with the conditioned carbon anions before they can form the desired nanocarbon structures may be particularly important in creating and maintaining the desired collection atmosphere. Thus, a preferred process includes first purging the chamber **107** by directing a suitable purge gas such as argon or some other noble gas or an inert gas from purge supply **129** to chamber **107**. A separate purge arrangement may alternatively or additionally be included in the system with a purge inlet directly in chamber **107** to prevent having to run the purge gas through the reactant liquid.

The flow regime of effluent exiting the reactant liquid and flowing through collection chamber **107** may be important for allowing the conditioned carbon anions to bond together to produce the desired carbon nanostructures without extrane-

ous atoms becoming incorporated in the structures. It is believed that a low velocity turbulent flow regime over collection surface **110** (that is, a flow producing eddy currents over the collection surface) best facilitates the production of carbon nanostructures without incorporating heavier atoms (such as metals) that may escape from the reactant liquid bath. It may also be possible to adjust the flow rate and composition of effluent flowing over collection surface in order to encourage the incorporation of various atoms other than carbon in the carbon nanostructures produced at the collection surface. The invention encompasses numerous techniques for controlling the composition and flow rate of effluent through collection chamber **107** and over collection surface **110**. The relative amount of carbon-bearing feed material in the material injected at point **104** and the type or types of hydrocarbon materials injected may influence both flow rate and content of flow. An inert or noble gas may be injected together with the feed material from purge gas supply **129** or from some other supply to affect the flow rate of effluent through chamber **107** and the content of the effluent.

Some forms of the invention may purposefully inject one or more materials into the collection chamber **107** through a separate collection chamber input, that is, separate from effluent ejection area **108**, in order to affect the flow characteristics in the flow chamber and in order to provide desired materials to be incorporated in the carbon nanostructures. Such a separate collection chamber input may include a suitable tube such as the example tube **150** shown in FIG. **1** which traverses a collection chamber wall and which includes an injection end **151** at a point to direct injected materials against collection surface **110** as effluent flows up from the reactant liquid **105** and passes over the collection surface. Particles of seed material may also be injected into collection chamber **107** with such an injection conduit. These particles of seed material may be injected prior to enabling the conditioned carbon anions to flow across collection surface **110** or while conditioned carbon anions are flowing across the collection surface.

Numerous other variations may be employed to produce the desired flow regime and flow characteristics through collection chamber **107**. Two methods are employed in apparatus **100** shown in FIG. **1**. One method employs deflection surface **140** to deflect effluent escaping from the reactant liquid at effluent ejection area **108**. This deflection is preferably produced anywhere from just above the surface of the reactant liquid to approximately three feet above the surface of the reactant liquid. Other types of deflection surfaces or features may also be employed according to the present invention. The other flow regime and characteristic affecting technique used the apparatus shown in FIG. **1** comprises providing collection surface **110** in a transverse plane with respect to device vertical axis **V** along which the effluent initially flows as it escapes the reactant liquid. Providing this transverse collection surface **110** produces a low pressure area on the collection surface in an area near the rightmost edge in FIG. **1**. The low pressure area created as effluent flows over the rightmost upper edge of collection structure **138** in FIG. **1** is believed to encourage the collection of conditioned carbon anions at that location of collection surface **110** and the production of carbon nanostructures at that location. It will be appreciated that numerous different collection surface profiles or contours may be employed to encourage the desired collection of conditioned carbon anions and self-assembly of nanostructures. For example, collection surface **110** may include one or more projections and/or indentations to produce the desired flow characteristics across the collection surface.

Any number of reactant liquids may be used to react the feed materials or feed material constituents according to the present invention. A preferred reactant liquid comprises liquid aluminum either alone or with other metals as disclosed in U.S. Pat. No. 5,000,101, which is also incorporated herein in its entirety. Temperatures may preferably range from approximately 650 degrees Celsius to approximately 950 degrees Celsius for reactant metals incorporating a substantial fraction of aluminum. Other reactant liquids may be used within different temperature ranges sufficient to liberate carbon atoms and place them in the desired chemically excited state as conditioned carbon anions for assembly into nanostructures at collection surface **110**. The invention encompasses any liquid that either reacts with the feed material or otherwise causes carbon atoms to be liberated from the feed material and excited to conditioned carbon anions. The carbon atoms may be liberated by chemical reduction (as in the case of a reactant liquid made up predominantly of aluminum), by chemical oxidation, by providing chemically neutral electron reduction potentials, or by applying sufficient kinetic energy (through heat) to break the carbon bonds to other atoms in the feed molecules, or by any of these mechanisms. Liberated carbon atoms may then be converted to the desired conditioned carbon anions by any suitable process, preferably by heat applied through the reactant liquid. The reactant liquid may be a metal, acid, base, salt, or any combination of these. The temperature of the particular liquid will depend upon the particular reaction required to liberate carbon atoms from the feed material and the nature of the reactant liquid itself. For example, chemically neutral liquids that liberate carbon atoms by heat alone may be held at very high temperatures to produce the desired carbon liberation, and excitation to conditioned carbon anions. Temperatures on the order of approximately 1500 degrees Celsius or more may be required for carbon liberation and excitation by heat alone.

Collection surface **110** is also preferably maintained in a similar temperature range as the reactant liquid, and most preferably at a temperature just below the reactant liquid temperature, for example, approximately fifty (50) degrees Celsius or less below the liquid reactant temperature. Thus, the collection surface **110** and collection chamber **107** in areas near the collection surface will be isothermic or nearly isothermic with respect to the reactant liquid. It is believed that these reactant liquids, and temperatures, together with the reaction pressure and contact time with the reactant liquid not only liberate the carbon atoms from the hydrocarbon feed material but also places the liberated carbon in the excited state as conditioned carbon anions. The reactant liquid is also believed to surround the liberated carbon atoms while they are still in the reactant liquid to maintain the carbon atoms in the chemically excited state as conditioned carbon anions and prevent them from phase changing to a ground state before they have a chance to self-assemble into the desired nanostructures at the collection surface **110**. The conditions are maintained at the collection surface according to the present invention so that these conditioned carbon anions phase change to a ground state as they bond covalently with other carbon atoms at the collection surface to form the desired carbon nanostructures.

It will be appreciated that some carbon that escapes the reactant liquid may also be diatomic carbon and double or triple bonded carbon. As used in this disclosure and the accompanying claims, "liberated carbon atoms" includes single atom carbon, diatomic carbon, and other two-carbon combinations such as two-carbon double bonded structures and two-carbon triple bonded structures. All of the liberated carbon atoms as well as all surviving carbon molecules escap-

ing the reactant liquid will also be chemically excited, that is, will have active electrons. Some of the two-carbon combinations and/or other surviving carbon molecules that may escape the reactant liquid may be incorporated, together with single, chemically excited carbon atoms, into molecularly combined carbon nanostructures within the scope of the present invention.

The present invention may use any number of carbon-bearing compounds as the feed material or as part of the feed material. Preferred forms of the invention utilize hydrocarbon compounds including single-bonded carbon either predominantly or exclusively. However, compounds including double and triple bonded carbon may be used according to the invention provided sufficient contact time with the reactant liquid to liberate carbon atoms and energize them to conditioned carbon anions for assembly into carbon nanostructures, or to produce chemically excited carbon molecules for assembly into carbon nanostructures. Some forms of the invention may adjust the content of the various carbon-bearing materials in a feed material mixture to provide a desired concentration of liberated single carbon atoms and liberated carbon molecules for incorporation into the desired carbon nanostructures. For example, the feed materials may be manipulated so that the effluent escaping the reactant liquid includes carbon in desired relative concentrations of single carbon atoms and double bonded carbon molecules.

It is also noted that some reactant liquids are capable of liberating carbon atoms from highly stable forms of carbon. For example, the preferred reactant liquid made up of aluminum or alloys of aluminum has the capability of liberating carbon atoms from even highly stable forms of carbon such as graphite and carbon nanostructures given sufficient contact time. Thus, some types of reactant liquids, whether they operate by chemical reduction, chemical oxidation, pyrolysis, or by reactions from acids, bases, or salts, may be used to destroy carbon nanostructures and recycle the carbon atoms from these materials in different types of carbon materials. In one aspect of the present invention, carbon nanostructure materials may be introduced into a reactant liquid such as liquid aluminum or liquid aluminum alloy at 650 to 950 degrees Celsius to isolate conditioned carbon anions from the carbon nanostructure material. The conditioned carbon anions may then be directed to a recovery area where the liberated carbon may be recovered. The recovery area may comprise a collection chamber such as chamber **107** in FIG. **1** where the carbon anions may self-assemble into new carbon nanostructures. Alternatively, the recovery area may comprise a collection surface free area in which the carbon anions are encouraged to phase change to a ground state without self-assembly into carbon nanostructures.

Tests which were conducted according to the present invention may be described with reference to the test apparatus **600** shown diagrammatically in FIG. **6**. This test apparatus **600** included a vessel **601** containing liquid reactant metal **602** made up of predominantly aluminum together with a number of other metals at about 930 degrees Celsius. The liquid reactant metal **602** was continuously circulated to and from a heating chamber not shown in FIG. **6** with a stirring device also not shown in the figure. An injection/collection structure included in test apparatus **600** was made up of an injection conduit **604** that extended down from a top wall **605** to an injection point **606** below the level **607** of reactant metal **602**. Subsurface deflecting elements **608** helped prevent reaction products **609** from escaping the bath too quickly. A collection structure **610** included a rectangular plate generally centered in vessel **601**. Effluent escaping from the reactant metal **602** traversed the surface of the metal at level **607**

in areas A and in small gaps G between injection conduit **604** and collection structure/plate **610**. During the collection part of the test, plate **610** was mostly submerged in liquid metal **602** leaving at most about one-half inch of the plate thickness above level **607**.

In the tests, once the injection conduit/collection structure was in place in vessel **601**, argon gas was injected through input line **612** and ultimately through conduit **604** and the reactant metal to displace air and any other gasses trapped in the area between level **607** and top **605** which formed the collection area of the apparatus. Once the collection area was purged with argon gas, methane was injected through input **614** at a rate of approximately four liters per minute for between thirty and forty-eight hours. Thereafter, acetylene gas and motor oil were also pumped through conduit **604**. The injection conduit/collection structure was then removed from vessel **601** and allowed to cool in open air. Black soot-like material was observed over substantially the entire upper surface of collection plate **610**. This material was scraped off plate **610** in several areas and observed through a scanning electron microscope down to a resolution of approximately one micron and a transmission electron microscope at up to 200,000 times magnification. These observations showed single-walled carbon nanotubes, double-walled carbon nanotubes, nanofibers, and carbon nanoropes in the sample material.

FIGS. **7** and **8** may be used to describe carbon nanostructures that may be produced from the conditioned carbon anions generated beneath a surface of a reactant liquid according to the present invention. A novel quality of carbon nanostructures produced from reactant liquid-generated conditioned carbon anions is that substantially all other materials, including even hydrogen may be excluded from the resulting carbon nanostructures. The resulting carbon nanostructures are made up purely of hexagonally arranged carbon atoms with each carbon atom having three covalent bonds to adjoining carbon atoms and one unbound pi electron. FIG. **7** shows a small portion carbon nanostructure made up of a single layer of hexagonally arranged carbon atoms **701**. This structure may be planar or may be a portion of a nanotube wall. Each carbon atom **701** includes three covalent bonds **702** to adjoining carbon atoms **701**. Each carbon atom **701** also includes one unbound pi electron **703** having an orbital extending generally at a right angle to the plane of the adjacent hexagonal arrangement. The unbound pi electrons **703** are shown in the view of FIG. **7** as extending uniformly on one side of the hexagonal rings. However, it will be appreciated that carbon nanostructures according to the invention may be formed with unbound pi electrons arranged on each side of the hexagonal rings. That is, some unbound pi electrons may extend in the direction shown in FIG. **7**, while others may extend in the opposite direction.

FIG. **8** shows a small portion of another carbon nanostructure made up of hexagonal rings of carbon atoms **801**. This structure, however, is made up of two distinct layers of hexagonally arranged carbon atoms, layer **802** and layer **803**. Each layer **802** and **803** may be planar or each may form part of a tubular structure, a double-walled nanotube. As in the structure of FIG. **7**, each carbon atom **801** is covalently bonded to three adjoining carbon atoms and includes an unbound pi electron **804** having an orbital extending generally perpendicular to the plane of the hexagonal structure. Again, the unbound pi electrons need not all extend on one side of the hexagonal structures, but may be interleaved or otherwise extend on opposite sides of the hexagonal structures.

It is believed that the hydrogen-free and impurity-free carbon nanostructures illustrated in FIGS. **7** and **8** are produced by two cooperating factors according to the present invention. First, the conditioned carbon anions and other materials, such as hydrogen, released from a carbon-bearing feed material are maintained in an isolated state beneath the surface of the reactant liquid, each completely surrounded by atoms of the reactant liquid, as individual separate "islands" in the reactant liquid. Thus, there is no possibility of contaminant incorporation with the carbon in the reactant liquid itself. Second, once the conditioned carbon anions and any energized carbon molecules escape from the bath to the isothermic or nearly isothermic nanostructure collection surface (**110** in FIG. **1**), the energy states of all the non-carbon atoms remains such that the non-carbon atoms form antibonding molecular orbitals with respect to carbon. This formation of molecular orbitals in the non-carbon atoms prohibits the non-carbon atoms, including hydrogen and any other atomic contaminants, from bonding with the eluding carbon anions and molecules. Rather, the eluding conditioned carbon anions rapidly phase change into carbon nanostructures while hydrogen atoms and other non-carbon atoms eluding from the reactant liquid are carried on as effluent that eventually exits the system through outlet conduit **135** in the embodiment of FIG. **1**.

As used herein, whether in the above description or the following claims, the terms "comprising," "including," "carrying," "having," "containing," "involving," and the like are to be understood to be open-ended, that is, to mean including but not limited to. Only the transitional phrases "consisting of" and "consisting essentially of," respectively, shall be considered exclusionary transitional phrases, as set forth, with respect to claims, in the United States Patent Office Manual of Patent Examining Procedures (Eighth Edition, August 2001 as revised September 2007), Section 2111.03.

Any use of ordinal terms such as "first," "second," "third," etc., in the claims to modify a claim element does not by itself connote any priority, precedence, or order of one claim element over another, or the temporal order in which acts of a method are performed. Rather, unless specifically stated otherwise, such ordinal terms are used merely as labels to distinguish one claim element having a certain name from another element having a same name (but for use of the ordinal term).

The above described preferred embodiments are intended to illustrate the principles of the invention, but not to limit the scope of the invention. Various other embodiments and modifications to these preferred embodiments may be made by those skilled in the art without departing from the scope of the present invention.

The invention claimed is:

1. A method including:

- (a) introducing a carbon-bearing material into a reactant liquid;
- (b) isolating carbon atoms from the carbon-bearing material as conditioned carbide anions located within the reactant liquid;
- (c) providing a collection area which contains at least one collection surface;
- (d) enabling the conditioned carbide anions to traverse a surface of the reactant liquid and travel into the collection area over the at least one collection surface contained in the collection area;
- (e) introducing a material into the collection chamber through a separate collection chamber input as the conditioned carbon anions travel over the collection surface, the separate collection chamber input having an injection end positioned within the collection chamber so that

13

the material introduced into the collection chamber through the separate collection chamber input is directed against the collection surface as the conditioned carbon anions travel over the collection surface; and

(f) removing carbon nanostructures from the collection chamber.

2. The method of claim 1 wherein the reactant liquid is made up of one or more liquid metals.

3. The method of claim 2 wherein the reactant liquid includes predominantly aluminum.

4. The method of claim 3 wherein the reactant liquid is held at a temperature of approximately 900 degrees Celsius.

5. The method of claim 1 wherein the reactant liquid isolates carbon atoms from the carbon-bearing material by chemical reduction, chemical oxidation, or pyrolysis, or by reactions from acids, bases, or salts.

6. The method of claim 1 wherein the material injected into the collection chamber through the separate collection chamber input includes a seed material for the formation of carbon nanostructures.

7. The method of claim 1 wherein the reactant liquid comprises a liquid metal made up predominantly of aluminum and held at a temperature between approximately 650 degrees Celsius and approximately 950 degrees Celsius, and the collection surface is at a temperature no more than fifty (50) degrees Celsius below the temperature of the reactant liquid.

8. The method of claim 1 wherein the carbon-bearing material includes carbon nanostructures.

9. The method of claim 1 wherein the carbon-bearing material includes single carbon bonds exclusively.

10. A method including:

(a) introducing a carbon-bearing material into a reactant liquid;

(b) isolating carbon atoms from the carbon-bearing material as conditioned carbide anions located within the reactant liquid;

(c) enabling the conditioned carbide anions to traverse a surface of the reactant liquid and travel into a collection area adjacent to the reactant liquid;

(d) introducing a seed material into the collection chamber as the conditioned carbon anions travel into the collection chamber, the seed material comprising a material which encourages the assembly of carbon nanostructures from the conditioned carbon atoms in the collection area; and

(e) removing carbon nanostructures from the collection chamber.

14

11. The method of claim 10 further including providing a collection surface within the collection area.

12. The method of claim 11 wherein the seed material is introduced into the collection chamber through a separate collection chamber input as the conditioned carbon anions travel over the collection surface, the separate collection chamber input having an injection end positioned within the collection chamber so that the seed material is directed against the collection surface as the conditioned carbon anions travel over the collection surface.

13. The method of claim 12 wherein the carbon-bearing material includes single carbon bonds exclusively.

14. The method of claim 11 wherein the reactant liquid comprises a liquid metal made up predominantly of aluminum and held at a temperature between approximately 650 degrees Celsius and approximately 950 degrees Celsius, and the collection surface is at a temperature no more than fifty (50) degrees Celsius below the temperature of the reactant liquid.

15. An apparatus for producing carbon nanostructures, the apparatus including:

(a) a reactant liquid vessel for containing a reactant liquid at a reactant liquid level;

(b) a feed material injector having an outlet end positioned within the reactant liquid vessel at a point below the reactant liquid level;

(c) a collection chamber positioned to receive effluent escaping from the reactant liquid in the reactant liquid vessel;

(d) a collection structure, the collection structure including a collection surface having at least a portion which is spaced apart from side walls of the collection chamber and which resides in the collection chamber at a position above the reactant liquid level; and

(e) a separate collection chamber input having an injection end positioned in the collection chamber so as to direct a material flowing out of the injection end against the collection surface.

16. The apparatus of claim 15 further including a reaction chamber located within the reactant liquid vessel and having an upper surface below the reactant liquid level of the reactant liquid vessel.

17. The apparatus of claim 15 wherein the collection structure is suspended in the collection chamber from a support extending from a top of the collection chamber.
