(57) **ABSTRACT**

A liquid crystal display structure includes a first substrate panel, a second substrate panel, and a liquid crystal layer between the first substrate panel and the second substrate panel. Pixel portions, formed by respective electrodes for applying a voltage to the liquid crystal layer, include a transparent substrate panel, an organic insulating layer, a patterned reflective layer, a dielectric layer, a transparent conductive layer and a thin film transistor. The organic insulating layer is formed over the transparent substrate panel. The patterned reflective layer is formed over the organic insulating layer exposing a portion of the organic insulating layer. The dielectric layer is formed over the patterned reflective layer. The dielectric layer has a smooth upper surface. The transparent conductive layer is over the dielectric layer. The transparent conductive layer is connected to the thin film transistor so that the thin film transistor can drive the transparent conductive electrode.

## LIQUID CRYSTAL DISPLAY STRUCTURE

## CROSS-REFERENCE TO RELATED APPLICATION

This application is a divisional of an application Ser. No. 10/065,091, filed on Sep. 17, 2002, now pending, which claims the priority benefit of Taiwan application serial no. 90126138, filed Oct. 23, 2001. The full disclosure of each of the above-mentioned patent applications is hereby incorporated herein by reference and made a part of this specification.

## BACKGROUND OF THE INVENTION

## 1. Field of Invention

The present invention relates to a liquid crystal display (LCD) structure. More particularly, the present invention relates to a reflective and transreflective type of liquid crystal display or liquid crystal display structure with excellent legibility and display efficiency.

## 2. Description of Related Art

In recent years, the applications of liquid crystal display (LCD) are far and wide following full integration with various electronic device packages. Functional capacity and complexity of typical LCD such as liquid crystal monitors and PDAs also expand with time. In general, LCD devices may be categorized into three major types, namely, the reflective type, the transmissive type and the transreflective type.

FIG. 1 is a cross-sectional view of one conventional pixel portion of the transreflective liquid crystal display device. As shown in FIG. 1, the liquid crystal display device includes an upper glass panel **10a**, a lower glass panel **10b**, an upper polarizing film **11a**, a lower polarizing film **11b**, an electrode structure **12**, a liquid crystal layer **14**, a color filter **16**, a transparent conductive layer **20**, an organic insulating layer **26**, a thin film transistor **28** and a back light system **29**. The upper polarizing film **11a** is on the upper surface of the upper glass panel **10a** and the lower polarizing film **11b** is on the lower surface of the lower glass panel **10b**. The electrode structure **12**, the liquid crystal layer **14**, the color filter **16** and the transparent conductive layer **20** are all enclosed within the space between the upper glass panel **10a** and the lower glass panel **10b**. The electrode structure **12** is composed of a reflective electrode **22** and a transmissive electrode **20**. The transmissive electrode **20** can be, for example, an indium-tin-oxide (ITO) layer. The color filter **16** is a layer formed on the interior flat surface of the upper glass panel **10a**. Meanwhile, the electrode structure **12** is formed on the interior flat surface of the lower glass panel **10b**. The organic insulating layer **26** underneath the reflective electrode **22** has an uneven surface. The surface of the organic insulating layer **26** includes a plurality of protrude/recess structures **26a** (or bumps). The thin film transistor (TFT) is formed over the lower glass panel **10b**. The thin film transistor **28** includes a gate electrode **28a**, a source terminal **28b** and a drain terminal **28c**. The back lighting system **29** is mounted on the exterior surface of the lower polarizing film **11b**.

To increase the efficiency of reflection in FIG. 1, the protrude/recess structure **26a** of the organic insulating layer **26** is specially designed to have an undulating surface. Due to the non-planarity of the reflective electrode **22** surface, liquid crystal misalignment and non-uniformity of liquid crystal cell gap inside the pixels can be detrimental to the display performance. Ultimately, quality of the liquid crystal display product is compromised. From FIG. 1, the reflective electrode **22** has an undulating shape and is made of a material having a high light reflection efficiency. When light is emanated from

the back light system **29** behind the liquid crystal layer **14**, the light passes through the liquid crystal layer **14** only once and exits out from the display surface. When a beam of light incident on the surface of the liquid crystal display from the viewer's side, the light passes through the liquid crystal layer **14** and is reflected by the reflective electrode **22** having the undulating shape, and passes through the liquid crystal layer **14** again to exit from the surface of the liquid crystal display. The light is reflected at various angles due to the undulating shaped reflective electrode **22**. The incident/reflection angles are measured with respect to the normal of the transparent substrate **10b** (i.e. the line perpendicular to the surface of the transparent substrate **10b**) in the plane of 6 o'clock and 12 o'clock. From experimental measurements for an incident light  $30^\circ$  from normal in the 12 o'clock direction, the light beam reflected from the display in a range between  $0^\circ$  and  $30^\circ$  in the 6 o'clock direction is the most effective condition for a viewer. When the reflective angle of the light beam greater or less than this range, the viewing condition is poor for the viewer.

Hence, reflected lights at various angles outside the range are not effective for viewing. The reflected lights at various angles are reflected from various parts of the undulating surface of the reflection electrode. Therefore, if we only utilize the portions of the reflector surface which contributes to the useful reflected lights and convert the nonuseful parts of the reflector into transmissive region by removing the reflectors, the efficiency of the LCD can be significantly improved.

## SUMMARY OF THE INVENTION

Accordingly, one object of the present invention is to provide a liquid crystal display structure capable of minimizing liquid crystal misalignment in the liquid crystal layer and liquid crystal cell gap non-uniformity problem.

A second object of this invention is to provide a liquid crystal display structure having excellent legibility and display efficiency under any surrounding lighting levels.

A third object of this invention is to provide a liquid crystal display structure having much better legibility and display efficiency under any lighting levels and less misalignment in a liquid crystal layer and reduced liquid crystal cell gap non-uniformity problems.

To achieve these and other advantages and in accordance with the purposes of the invention, as embodied and broadly described herein, the invention provides three liquid crystal display (LCD) structures which can improve the viewing performances of the LCDs.

The first LCD structure is a reflective type of liquid crystal display. One pixel portion of the first LCD structure includes a first substrate panel, an organic insulating layer, a conformal reflection layer, a dielectric layer, a first transparent conductive layer, a thin film transistor, a second substrate panel, a second transparent conductive layer and a liquid crystal layer.

The first substrate panel, for example, can be a transparent glass panel. The organic insulating layer is formed over the first substrate panel and made from a material such as acrylic resin, photosensitive resin, polyimide, polymer or BCB. The surface of the organic insulating layer has a plurality of protrude/recess structures or bumps. The conformal reflection layer is formed over the organic insulating layer and made from a highly reflective metallic material such as aluminum or silver or a highly reflective non-metallic material. The conformal reflection layer serves as a non-planar reflecting surface due to the presence of the protrude/recess structures or bumps. The dielectric layer is formed over the conformal reflection layer. The dielectric layer may have a planar surface

or a surface having a planarity much better than the surface containing the bumpy structures for planarizing the metallic reflection layer. Furthermore, the dielectric layer may be a color filter capable of replacing the color filter close to the upper glass panel. If the dielectric layer is a transparent insulating layer, the color filter close to the upper glass panel may still be used. The first transparent conductive layer is formed over the dielectric layer. The first transparent conductive layer serves as an electrode. The thin film transistor is formed over the first substrate. The thin film transistor has a gate electrode, a source terminal and a drain terminal. The first transparent conductive layer electrode is connected to the thin film transistor so that the thin film transistor may drive the first transparent conductive layer electrode. The second substrate panel is aligned to the first substrate panel. The second transparent conductive layer is formed on the lower surface of the second substrate panel. The liquid crystal layer is sandwiched between the second transparent conductive layer and the first transparent conductive layer.

Since a material film having a non-planar surface is an essential aspect of the LCD structure but may lead to liquid crystal misalignment and liquid crystal cell gap non-uniformity problems, a dielectric layer having a relatively planar upper surface is formed over the material film. The dielectric layer can be a color filter layer or a transparent insulating layer. A transparent conductive layer is later formed over the dielectric layer. With this structural arrangement, the liquid crystal layer has a uniform thickness throughout and hence problems caused by having a non-planar reflection layer are avoided.

To achieve these and other advantages and in accordance with the purpose of the invention, as embodied and broadly described herein, the invention provides a liquid crystal display (LCD) structure, which utilizes the portions of the reflector surface which contributes to the useful reflected lights and convert the nonuseful parts of the reflector into transmissive region by removing the reflectors, the efficiency of the LCD can be significantly improved. The LCD structure is a transmissive (transmissive/reflective) type of liquid crystal display. One pixel portion of the second LCD structure includes a first substrate panel, an organic insulating layer, a plurality of conformal transparent conductors, a plurality of conformal reflectors, a thin film transistor, a second substrate panel, a second transparent conductive layer, a color filter layer, a liquid crystal layer and a back lighting system.

The first substrate panel, for example, can be a transparent glass panel. The organic insulating layer is formed over the first substrate panel and made from a material such as acrylic resin, photosensitive resin, polyimide, polymer or BCB. The surface of the organic insulating layer has a plurality of protrude/recess structures or bumps. Each protrude/recess structure can be divided into two regions, a first region and a second region, according to the preferable viewing angle for reflection. The first region is an area for forming the reflection layer and the second region is an area for forming the transmissive layer. The first region and the second region are alternately laid. The conformal transparent conductors are formed over a portion of the organic insulation layer. The plurality of reflectors is formed over the organic insulating layer and/or the conformal transparent conductors. The reflectors expose a portion of the conformal transparent conductors. The transparent conductors and the reflectors are alternately laid with some regions overlapped, thereby forming a continuous electrical connection. Materials constituting the reflectors include highly reflective metallic materials such as aluminum or silver. Each reflector covers at least a portion of the first region. There is no metallic material over the

second region and hence exposes the transparent conductors. Such exposed transparent conductors occupy roughly 1% to 60% of the overall area of the organic insulating layer. Thus, the reflectors serve as reflective electrodes while the transparent conductors serve as transmissive electrodes. The reflectors are constructed, for example, by forming a patterned reflective layer over the conformal transparent conductive patches or directly forming on the organic insulating layer. Alternatively, the reflectors are constructed by forming the patterned reflective layer over a portion of the organic insulating layer and a portion of the transparent conductors. To reduce electrochemical reaction due to direct contact between the transparent conductors and the aluminum or silver reflectors, a buffering layer, such as a molybdenum layer, may be introduced into the interface between the transparent conductors and the reflectors. The thin film transistor is formed over the first substrate. The thin film transistor has a gate electrode, a source terminal and a drain terminal. The transmissive electrode or the reflective electrode is connected to the thin film transistor so that the thin film transistor may drive the display electrodes. The second transparent conductive layer is formed on the lower surface of the second substrate panel. The color filter layer is formed over the second substrate panel and the second transparent conductive layer is formed over the color filter layer. The liquid crystal layer is sandwiched between the second transparent conductive layer and the first substrate panel. The back lighting system is mounted outside the first substrate panel facing the other side of the second substrate panel. A portion of the light emitted from the back lighting system passes through the transmissive electrode while another portion of the light reflects back from the reflective electrode and is re-used.

The division into a first region and a second region is based preferably according to the following relationship: for an incoming beam of light impinging at negative 30° to the normal (12 o'clock direction) of the surface of a reflection layer with protrude/recess structures, reflected light having a viewing angle between 0° to 30° are most suitable for a human observer (an angle measured from a normal line perpendicular to the panel, 6 o'clock direction). This portion having an angular range that corresponds with the protrude/recess structures defines the first region. When the distribution of reflected light falls upon other viewing range so that human eyes are difficult to observe, this portion having a viewing angle that corresponds to the protrude/recess structures defines the second region.

This invention also provides a third liquid crystal display (LCD) structure. The third LCD structure is a transmissive (transmissive/reflective) type of liquid crystal display. The third LCD structure includes a first substrate panel, an organic insulating layer, a reflective block layer, a dielectric layer, a first transparent conductive layer, a thin film transistor, a second substrate panel, a second transparent conductive layer, a color filter layer, a liquid crystal layer and a back lighting system.

The first substrate panel, for example, can be a transparent glass panel. The organic insulating layer is formed over the first substrate panel and made from a material such as acrylic resin, photosensitive resin, polyimide, polymer or BCB. The surface of the organic insulating layer has a plurality of protrude/recess structures or bumps. Each protrude/recess structure can be divided into two regions, a first region and a second region, according to the viewing angle. The plurality of reflectors is formed over the organic insulating layer so that a portion of the organic insulating layer is exposed. The reflectors are made using a highly reflective metallic material such as aluminum or silver or a highly reflective non-metallic

material. Each reflective block covers at least a portion of the first region. There are no reflectors over the second region and hence exposes the organic insulating layer. Such exposed organic insulating layer occupies roughly 1% to 60% of the overall area of the transparent conductive layer. Thus, the reflectors serve as reflective regions while the exposed organic insulating layer serves as transmissive regions. The reflectors are constructed, for example, by forming a patterned reflective layer over the organic insulating layer. The dielectric layer such as a color filter layer or a transparent insulating material layer is formed over the reflectors and the exposed organic insulating layer. The dielectric layer has a surface with a higher degree of planarity than the surface of the original protrude/recess structures, thereby smooth out the transmissive layer. The first transparent conductive layer is formed over the dielectric layer. The thin film transistor is formed over the first substrate. The thin film transistor has a gate electrode, a source terminal and a drain terminal. The first transparent conductive layer is connected to the thin film transistor so that the thin film transistor may drive the first transparent conductive layer. The second substrate panel is aligned to the first substrate panel. The color filter layer is formed over the second substrate panel (if the dielectric layer has color filtering capability, this color filter layer may be omitted). The second transparent conductive layer is formed over the second substrate panel or the color filter layer, if present. The liquid crystal layer is sandwiched between the second transparent conductive layer and the first transparent conductive layer. The back lighting system is mounted on the first substrate panel facing the other side of the second substrate panel. A portion of the light emitted from the back lighting system penetrates the transmissive electrode while another portion of the light reflects back from the reflective electrode and is re-used.

It is to be understood that both the foregoing general description and the following detailed description are exemplary, and are intended to provide further explanation of the invention as claimed.

#### BRIEF DESCRIPTION OF THE DRAWINGS

The accompanying drawings are included to provide a further understanding of the invention, and are incorporated in and constitute a part of this specification. The drawings illustrate embodiments of the invention and, together with the description, serve to explain the principles of the invention. In the drawings,

FIG. 1 is a cross-sectional view of a conventional liquid crystal display device;

FIG. 2 is a schematic cross-sectional view showing a first type of one pixel portion of a liquid crystal display structure according to a first preferred embodiment of the invention;

FIG. 3 is a graph showing the relationship between reflectivity (R) and viewing angle for a conventional reflective liquid crystal display;

FIG. 4 is a cross-sectional view showing a preferred embodiment of a microscopic structure of the transmissive film inside the liquid crystal structure shown in FIG. 2;

FIGS. 5 and 6 are schematic cross-sectional view and top view of a second type of one pixel portion of a liquid crystal display structure according to a second preferred embodiment of the invention; and

FIG. 7 is a schematic cross-sectional view showing a third type of one pixel portion of a liquid crystal display structure according to a third preferred embodiment of the invention.

#### DESCRIPTION OF THE PREFERRED EMBODIMENTS

Reference will now be made in detail to the present preferred embodiments of the invention, examples of which are illustrated in the accompanying drawings. Wherever possible, the same reference numbers are used in the drawings and the description to refer to the same or like parts.

FIG. 2 is a schematic cross-sectional view showing a first type of one pixel portion of a liquid crystal display structure according to a first preferred embodiment of this invention. A first glass panel or a first substrate panel **50b** and a second glass panel or a second substrate panel **50a** (the first glass panel **50b** is the lower glass panel and the second glass panel **50a** is the upper glass panel) are provided. The first glass panel **50b** and the second glass panel **50a** together enclose all the component layers, including layers such as a liquid crystal layer **54** and a color filter layer **84**, of a liquid crystal display (LCD). A quarter wave plate, a phase compensation plate and a polarizer composed of a group of polarizing panels (not shown in FIG. 2) are attached to the opposite side of the second glass panel **50a** with the liquid crystal layer **54**. An organic insulating layer **66** is formed over the first substrate panel **50b**. A dielectric layer may also form between the organic insulating layer **66** and the first substrate board **50b**. The organic insulating layer **66** is made from a material including, for example, acrylic resin, photosensitive resin, polyimide, polymer or BCB. The upper surface of the organic insulating layer **66** has a plurality of protrude/recess structures **66a** or bumps. A conformal reflective layer **82** is formed over the organic insulating layer **66**. The conformal reflective layer **82** is made from a highly reflective material including, for example, aluminum or silver. The conformal reflective layer **82** serves as a light reflection layer. However, due to the presence of bumps **66a** underneath, the conformal reflective layer **82** has a non-planar surface. The color filter layer **84** is formed over the conformal reflective layer **82**. The color filter layer **84** has a planar upper surface, thereby smoothing out the underlying conformal reflective layer **82**. A first transparent conductive layer **86** is formed over the color filter layer **84**. The LCD structure further includes a thin film transistor **68** above the first substrate panel **50b**. The thin film transistor **68** has a gate electrode **68a**, a source terminal **68b** and a drain terminal **68c**. The first transparent conductive layer **86** is connected to the thin film transistor **68** so that the thin film transistor **68** may drive the first transparent conductive layer **86**. The second substrate panel **50a** is above and parallel to the first substrate panel **50b**. A second transparent conductive layer **60** is formed under the second substrate panel **50a**. Finally, the liquid crystal layer **54** is formed between the second transparent conductive layer **60** and the first transparent conductive layer **86**. In a slightly different version of this embodiment, a transparent insulating material layer (not shown) may replace the color filter layer **84**. In this case, another color filter layer needs to be inserted between the second substrate panel **50a** and the second transparent conductive layer **60**.

In small portable reflective liquid crystal display products, users may adjust their viewing angle and prevent the eyes from gazing into surface glare. FIG. 3 is a graph showing the relationship between reflectivity (R) and viewing angle for a reflective liquid crystal display. For incoming light beam impinging at the liquid crystal display panel at  $-30^\circ$  from normal at 12 o'clock direction, the reflected lights can be divided into two regions. For example, the angular range from  $0^\circ$  to  $30^\circ$  from normal (at 6 o'clock direction) may be regarded as a normal usable range (I) or 'the first region' and

angular range from 30° to 90° may be regarded as a rarely used range (II) or 'the second region'. Obviously, the aforementioned setting of viewing angle 0° to 30° to 'the first region' and viewing angle 30° to 90° as 'the second region' is an approximation. In reality, the decision of the normal operating range often depends on the incoming light source, the background lighting conditions and the influence of the optimum reflection/transmission for the device.

The aforementioned analysis may be applied to the fabrication of micro-structural layer within the LCD panel. FIG. 4 is a cross-sectional view showing a preferred embodiment of a microscopic structure of the transfective film 30 inside the liquid crystal structure shown in FIG. 4. The transfective film 30 is divided into (I) first regions 30b and (II) second regions 30a. When a beam of light impinges upon the surface of a LCD panel at an angle, the reflected light that belongs to (I) the first regions 30b will fall upon viewing angular range 0° to 30° of 'the first region'. On the other hand, the reflected light that belongs to (II) the second regions 30a will fall upon viewing angular range 30° to 90°. This method of dividing area into regions according to the viewing angle can be applied to a transfective type of liquid crystal displays.

FIGS. 5 and 6 are schematic cross-sectional view and top view of a second type of one pixel portion of the liquid crystal display structure according to a second preferred embodiment of this invention. As shown in FIG. 5, a first glass panel 50b or a lower glass panel and a second glass panel 50a or an upper glass panel are provided. The first glass panel 50b and the second glass panel 50a together encloses all the internal layers of the liquid crystal display, for example, a transfective film 52, a liquid crystal layer 54 and a color filter layer 56. A quarter wave plate, a phase compensation plate and a polarizer plate composed of a group of polarizing films (not shown in FIG. 5) may be attached to the external facing sides of the first glass panel 50b and the second glass panel 50a away from the liquid crystal layer 54. An organic insulating layer 66 is formed over the first substrate panel 50b. A dielectric layer may also be formed between the organic insulating layer 66 and the first substrate board 50b. The pixel portion of the LCD structure further includes a thin film transistor 68 above the first substrate panel 50b. The thin film transistor 68 has a gate electrode 68a, a source terminal 68b and a drain terminal 68c.

The organic insulating layer 66 is made from a material including, for example, acrylic resin, photosensitive resin, polyimide, polymer or BCB. The upper surface of the organic insulating layer 66 further includes a plurality of protrude/recess structures 66a or bumps. Each protrude/recess structure 66a may be further sub-divided onto two different regions, including a first region (I) and a second region (II). For the purpose of improving efficiency of the LCD structure, the first region of the protrude/recess structure 66a is used to contribute to the useful reflected lights and the second region of the protrude/recess structure 66a is converted into a transmissive region by removing the reflectors. Alternatively, portions of the first region and the second region can be formed by first forming a transparent conductive layer over the entire protrude/recess structure 66a and then patterning reflective electrodes over region I to form a region contributing to the useful reflected lights. The region contributing to the useful reflected lights is the first region and the remaining exposed transparent conductive layer region is the second region. In another way, a conformal transparent conductive layer 64 can be formed at least over a portion of the organic insulating layer 66 to constitute the second region. A plurality of reflectors 62 are formed over the organic insulating layer 66 and/or over parts of the conformal transparent conductive layer 64 (as shown in FIG. 5 of the preferred embodiment, the reflec-

tors 62 are formed over the conformal transparent conductive layer 64, for example) such that a portion of the conformal transparent conductive layer 64 is exposed. Alternatively, the reflectors 62 can also be formed directly on portions of the undulating surface of the organic insulating layer 66 to form the first region and the conformal transparent conductive layer 64 can also be formed on remaining portions of the surface of the organic insulating layer 66 to form the second region. Either the reflectors 62 or the transparent conductive layer 64, or both, is/are connected to the thin film transistor 68 so that the thin film transistor 68 may drive the reflectors 62 and/or the transparent conductive layer 64.

The exposed transparent conductive layer 64 and the reflectors 62 are formed in an alternating array. The transparent conductive layer 64 and the reflectors 62 are arranged in such that some regions are overlapped (in FIG. 5, overlapping between the two is shown) to form a continuous electrically connected layer. The reflectors 62 are made from a highly reflective material such as aluminum or silver. To reduce electrochemical reaction due to direct contact between the transparent conductive layer 64 and the aluminum or silver reflectors 62, a buffer conductive layer (not shown), such as a molybdenum layer, may be introduced as an interface formed between the transparent conductive layer 64 and the reflectors 62. The exposed conformal transparent conductive layer 64 is roughly about 1% to 60% of the protrude/recess structure 66a occupied area. For example, each reflector 62 covers at least a portion of the first region (I) while the second region (II) is free of the reflectors 62, and hence the transparent conductive layer 64 is exposed. Thus, the reflectors 62 serve as reflective electrodes, and the transparent conductors 64 serve as a transmissive electrodes. The transmission layer (the first transparent conductors 64) or the reflective electrodes, or both, are connected to the thin film transistor 68 so that the thin film transistor 68 may drive both the first transparent conductive layer 64 and the reflective electrodes 62. The second substrate panel 50a is above and parallel to the first substrate panel 50b. The LCD structure also includes the color filter layer 56 formed over the second glass panel 50a. A second transparent conductive layer 60 is formed over the color filter layer 56. The liquid crystal layer 54 is formed between the second transparent conductive layer 60 and the first transparent conductive layer 50b. The LCD structure also has a back lighting system 69 attached to the other side of the first glass panel 50b opposite the second glass panel 50a. A portion of the light beam emitted from the back lighting system 69 passes through the transmission electrode 64. The remaining portion of the light is reflected back for re-use via the reflective electrode 62.

Furthermore, the following method may be used to divide the transfective layer into a first region (I) and a second region (II). Assume an incoming beam of light impinges upon the surface of a reflective layer fully covered with protrude/recess structures 66a. If the range of the reflected light falls within an angle between 0° to 30° or the viewing angle for best human observation, the portion of the protrude/recess structures 66a corresponding to such viewing angular range is defined as 'the first region' (I). On the other hand, if the reflected light falls within an angle between 30° to 90° or the worst viewing angle for human observer, the portion of the protrude/recess structures 66a corresponding to such viewing angular range is defined as 'the second region' (II). Obviously, the aforementioned setting of viewing angle 0° to 30° to 'the first region' and viewing angle 30° to 90° as 'the second region' is quite arbitrary. In reality, the decision of the normal operating range often depends on the incoming light

source, the background lighting conditions and the optimum reflection/transmission relationship.

As shown in FIG. 5, inside each liquid display pixel 70, the protrude/recess structures 66a have different shape and size distribution on the first glass panel 50b. Furthermore, each protrude/recess structure 66a is divided into first region (I) and second region (II) according to the viewing direction. The first regions (I) of the protrude/recess structures 66a are areas where the reflectors 62 (the reflective layer) are located. Similarly, the second regions (II) of the protrude/recess structures 66a are areas where the exposed transparent conductive layer 64 (the transmission layer) are located. The two together constitute a transfective film 52. In addition, a thin film transistor 68 that includes a gate electrode 68a, a source terminal 68b and a drain terminal 68c is formed on one edge of the liquid crystal pixel 70.

The invention also provides a liquid crystal display structure having a color filter layer above the reflective layer and the transmission layer so that the reflective layer and the transmission layer can have a planar surface. Aside from having excellent legibility and display efficiency, the LCD structure is able to minimize liquid crystal misalignment caused by an uneven reflective layer.

FIG. 7 is a schematic cross-sectional view showing a third type of one pixel portion of a liquid crystal display structure according to a third preferred embodiment of the invention. In FIG. 7, components identical to the ones in FIG. 5 are labeled identically. As shown in FIG. 7, a first glass panel 50b or a lower glass panel and a second glass panel 50a or an upper glass panel are provided. The first glass panel 50b and the second glass panel 50a together enclose all the internal layers of the liquid crystal display, for example, a transfective structure 80, a liquid crystal layer 54 and a color filter layer 76. A quarter wave plate, a phase compensation plate, and a polarizer composed of a group of polarizing panels (not shown in FIG. 5) may be attached to the external facing sides of the first glass panel 50b and the second glass panel 50a away from the liquid crystal layer 54. An organic insulating layer 66 is formed over the first substrate panel 50b. A dielectric layer may also exist between the organic insulating layer 66 and the first substrate board 50b. The organic insulating layer 66 is made from a material including, for example, acrylic resin, photosensitive resin, polyimide, polymer or BCB. The upper surface of the organic insulating layer 66 further includes a plurality of protrude/recess structures 66a or bumps. Each protrude/recess structure 66a may be further sub-divided into two different regions, including a first region (I) and a second region (II). A plurality of reflectors 74 is formed over the organic insulating layer 66 such that a portion of the organic insulating layer 66 is exposed. The reflectors 74 are made from a highly reflective material such as aluminum or silver. The exposed organic insulating layer 66 is roughly about 1% to 60% of the protrude/recess structure 66a area. For example, each reflector 74 covers at least a portion of the first region (I) while the second region (II) is free of the reflectors 74 and hence exposes the organic insulating layer 66. Thus, the reflectors 74 serve as reflective regions, and the organic insulating layer 66 serve as transmission regions. The reflectors 74 and the organic insulating layer 66 together form the transfective layer 80. The color filter film 76 is formed over the reflectors 74 and the exposed organic insulating layer 66. The color filter layer 76 has a smooth upper surface and hence evening out the undulating surface of the protrude/recess structures 66a. An insulating material layer may replace the color filter layer 76. A transparent conductive layer 78 is formed over the color filter layer 76 to serve as an electrode. The LCD structure further includes a thin film

transistor 68 above the first substrate panel 50b. The thin film transistor 68 has a gate electrode 68a, a source terminal 68b and a drain terminal 68c. The transparent conductive layer 78 is electrically connected to the drain electrode 68c through a via hole. In addition, a second transparent conductive layer 60 is formed over the second substrate panel 50a. The liquid crystal layer 54 is formed between the first transparent conductive layer 78 and the second transparent conductive layer 60. The LCD structure also has a back lighting system 69 attached to the other side of the first glass panel 50b opposite the second glass panel 50a. A portion of the light emitted from the back lighting system 69 penetrates through the transmission layer 66. The remaining portion of the light is reflected back for re-use via the reflective layer 74. In a slight variation of the embodiment, a transparent insulating material layer (not shown) may replace the color filter layer 76. In such case, another color filter film is needed between the second substrate panel 50a and the second transparent conductive layer 60.

It will be apparent to those skilled in the art that various modifications and variations can be made to the structure of the present invention without departing from the scope or spirit of the invention. In view of the foregoing, it is intended that the present invention cover modifications and variations of this invention provided they fall within the scope of the following claims and their equivalents.

What is claimed is:

1. A liquid crystal display (LCD) structure, comprising:
  - a first substrate panel, a second substrate panel, and a liquid crystal layer disposed between the first substrate panel and the second substrate panel, a plurality of pixel portions being formed with respective electrodes for applying a voltage to the liquid crystal layer, each of the pixel portions comprising:
    - an organic insulating layer over the first substrate panel, wherein a surface of the organic insulating layer has a plurality of bumps;
    - a patterned reflective layer conformably formed over the organic insulating layer such that portions of the organic insulating layer are exposed, wherein the exposed portions of the organic insulating layer are located within the plurality of bumps and the plurality of reflectors exposes about 1 to 60% of the overall organic insulating layer;
    - a color filter layer having a substantially planar upper surface, being completely covered the patterned reflective layer and the exposed portions of the organic insulating layer for smoothing out the patterned reflective layer;
    - a contact hole formed in the planar color filter layer, the conformal reflective layer and the organic insulating film; and
    - a first transparent conductive layer conformably formed over the color filter layer, wherein the first transparent conductive layer is connected to a thin film transistor through the contact hole in the planar color filter layer, the conformal reflective layer and the organic insulating film, and a first terminal of the thin film transistor is configured in the planar color filter layer while a second terminal of the thin film transistor is configured in the organic insulating layer.

2. The liquid crystal display structure of claim 1, wherein each bump is divided into a first region defined to reflect lights within a preferable observation range and a second region defined to reflect lights within a difficult-to-see range.

3. The liquid crystal display structure of claim 2, wherein each exposed portion of the organic insulating layer is only located within the second region of each bump, and no exposed portion is located outside the bump.

4. The liquid crystal display structure of claim 1, wherein the thin film transistor has a gate electrode, a source terminal and a drain terminal over the first substrate panel.

5. The liquid crystal display structure of claim 1, wherein the second substrate panel further includes a second transparent conductive layer over the second substrate panel. 5

6. The liquid crystal display structure of claim 1 further including a phase compensation plate and a polarizer on each exterior-facing side of the first substrate panel and the second substrate panel away from the liquid crystal layer. 10

7. The liquid crystal display LCD structure of claim 1, further comprising a back lighting system attached to the side of the first substrate panel on the other side of the second substrate panel such that a portion of the emitted light from the back lighting system passes through the reflectors. 15

8. The liquid crystal display structure of claim 1, wherein the first substrate panel includes a glass panel.

9. The liquid crystal display structure of claim 1, wherein a material for forming the reflectors includes aluminum, silver or a reflective non-conducting material. 20
