(51) **Int. Cl.**  
**H01L 21/44** (2006.01)

A method of making a semiconductor device includes providing a substrate, and forming a first conductive layer over the substrate. A patterned layer is formed over the first conductive layer. A second conductive layer is formed in the patterned layer. A height of the second conductive layer is greater than a height of the first conductive layer. The patterned layer is removed. A first bump and a second bump are formed over the first and second conductive layers, respectively, wherein the second bump overlaps the first bump, and wherein an uppermost surface of the second bump is vertically offset from an uppermost surface of the first bump. Bond wires are formed on the first and second bumps. The bond wires are arranged in a straight configuration. Lowermost surfaces of the first conductive layer and second conductive layer are substantially coplanar.

**SEMICONDUCTOR DEVICE AND METHOD  
OF FORMING VERTICALLY OFFSET BOND  
ON TRACE INTERCONNECTS ON  
DIFFERENT HEIGHT TRACES**

CLAIM TO DOMESTIC PRIORITY

The present application is a continuation of U.S. patent application Ser. No. 12/720,029, now U.S. Pat. No. 8,039,384, filed Mar. 9, 2010, and claims priority to the foregoing parent application pursuant to 35 U.S.C. §120.

FIELD OF THE INVENTION

The present invention relates in general to semiconductor devices and, more particularly, to a semiconductor device and method of forming vertically offset bond on trace (BOT) interconnects on different height traces.

BACKGROUND OF THE INVENTION

Semiconductor devices are commonly found in modern electronic products. Semiconductor devices vary in the number and density of electrical components. Discrete semiconductor devices generally contain one type of electrical component, e.g., light emitting diode (LED), small signal transistor, resistor, capacitor, inductor, and power metal oxide semiconductor field effect transistor (MOSFET). Integrated semiconductor devices typically contain hundreds to millions of electrical components. Examples of integrated semiconductor devices include microcontrollers, microprocessors, charged-coupled devices (CCDs), solar cells, and digital micro-mirror devices (DMDs).

Semiconductor devices perform a wide range of functions such as high-speed calculations, transmitting and receiving electromagnetic signals, controlling electronic devices, transforming sunlight to electricity, and creating visual projections for television displays. Semiconductor devices are found in the fields of entertainment, communications, power conversion, networks, computers, and consumer products. Semiconductor devices are also found in military applications, aviation, automotive, industrial controllers, and office equipment.

Semiconductor devices exploit the electrical properties of semiconductor materials. The atomic structure of semiconductor material allows its electrical conductivity to be manipulated by the application of an electric field or base current or through the process of doping. Doping introduces impurities into the semiconductor material to manipulate and control the conductivity of the semiconductor device.

A semiconductor device contains active and passive electrical structures. Active structures, including bipolar and field effect transistors, control the flow of electrical current. By varying levels of doping and application of an electric field or base current, the transistor either promotes or restricts the flow of electrical current. Passive structures, including resistors, capacitors, and inductors, create a relationship between voltage and current necessary to perform a variety of electrical functions. The passive and active structures are electrically connected to form circuits, which enable the semiconductor device to perform high-speed calculations and other useful functions.

Semiconductor devices are generally manufactured using two complex manufacturing processes, i.e., front-end manufacturing, and back-end manufacturing, each involving potentially hundreds of steps. Front-end manufacturing involves the formation of a plurality of die on the surface of a semiconductor wafer. Each die is typically identical and con-

2

tains circuits formed by electrically connecting active and passive components. Back-end manufacturing involves singulating individual die from the finished wafer and packaging the die to provide structural support and environmental isolation.

One goal of semiconductor manufacturing is to produce smaller semiconductor devices. Smaller devices typically consume less power, have higher performance, and can be produced more efficiently. In addition, smaller semiconductor devices have a smaller footprint, which is desirable for smaller end products. A smaller die size may be achieved by improvements in the front-end process resulting in die with smaller, higher density active and passive components. Back-end processes may result in semiconductor device packages with a smaller footprint by improvements in electrical interconnection and packaging materials.

Many semiconductor devices require a fine pitch between the interconnect structures, e.g., between bond wire bumps, for a higher interconnect density and input/output (I/O) terminal count. To increase the I/O terminal count, the bond wire bumps can be laterally offset, staggered, or zig-zag pattern extending from the signal traces. The lateral offset allows the bond wire bumps to be positioned closer together, i.e., small pitch, without electrically shorting adjacent terminals. However, the lateral offset also requires longer bond fingers in order to form the bond wire bumps, which consumes die area. In addition, the BOT must have a sufficiently wide trace pitch to prevent shorting between bumps. The space requirements limit use of smaller substrates and add materials cost.

SUMMARY OF THE INVENTION

A need exists to decrease bond wire bump pitch without increasing trace width or length of the bond fingers. Accordingly, in one embodiment, the present invention is a method of making a semiconductor device comprising the steps of providing a substrate and forming a first conductive layer over the substrate. A patterned layer is formed over the first conductive layer. A second conductive layer is formed in the patterned layer. A height of the second conductive layer is greater than a height of the first conductive layer. The patterned layer is removed. A first bump and a second bump are formed over the first and second conductive layers, respectively. The second bump overlaps the first bump. An uppermost surface of the second bump is vertically offset from an uppermost surface of the first bump.

In another embodiment, the present invention is a method of making a semiconductor device comprising the steps of providing a substrate and forming a first conductive layer over the substrate. A second conductive layer is formed over the substrate. A height of the second conductive layer is greater than a height of the first conductive layer. A first interconnect structure and a second interconnect structure are formed over the first conductive layer and the second conductive layer, respectively. An upper surface of the second interconnect structure is vertically offset from an upper surface of the first interconnect structure.

In another embodiment, the present invention is a method of making a semiconductor device comprising the steps of providing a substrate, and forming a first conductive layer over the substrate. A second conductive layer is formed over the substrate. A height of the second conductive layer is greater than a height of the first conductive layer. An interconnect structure is formed over the first and second conductive layers.

In another embodiment, the present invention is a semiconductor device comprising a substrate and a first conductive

layer disposed over the substrate. A second conductive layer is disposed over the substrate. The second conductive layer has a height greater than a height of the first conductive layer. A first interconnect structure and a second interconnect structure are disposed over the first conductive layer and the second conductive layer, respectively. An upper surface of the second interconnect structure is vertically offset from an upper surface of the first interconnect structure.

#### BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 illustrates a PCB with different types of packages mounted to its surface;

FIGS. 2a-2c illustrate further detail of the representative semiconductor packages mounted to the PCB;

FIGS. 3a-3j illustrate a process of forming vertically offset BOT interconnect sites on different height traces; and

FIGS. 4a-4b illustrate top and side views of the vertically offset BOT interconnect sites on different height traces.

#### DETAILED DESCRIPTION OF THE DRAWINGS

The present invention is described in one or more embodiments in the following description with reference to the figures, in which like numerals represent the same or similar elements. While the invention is described in terms of the best mode for achieving the invention's objectives, it will be appreciated by those skilled in the art that it is intended to cover alternatives, modifications, and equivalents as may be included within the spirit and scope of the invention as defined by the appended claims and their equivalents as supported by the following disclosure and drawings.

Semiconductor devices are generally manufactured using two complex manufacturing processes: front-end manufacturing and back-end manufacturing. Front-end manufacturing involves the formation of a plurality of die on the surface of a semiconductor wafer. Each die on the wafer contains active and passive electrical components, which are electrically connected to form functional electrical circuits. Active electrical components, such as transistors and diodes, have the ability to control the flow of electrical current.

Passive electrical components, such as capacitors, inductors, resistors, and transformers, create a relationship between voltage and current necessary to perform electrical circuit functions.

Passive and active components are formed over the surface of the semiconductor wafer by a series of process steps including doping, deposition, photolithography, etching, and planarization. Doping introduces impurities into the semiconductor material by techniques such as ion implantation or thermal diffusion. The doping process modifies the electrical conductivity of semiconductor material in active devices, transforming the semiconductor material into an insulator, conductor, or dynamically changing the semiconductor material conductivity in response to an electric field or base current. Transistors contain regions of varying types and degrees of doping arranged as necessary to enable the transistor to promote or restrict the flow of electrical current upon the application of the electric field or base current.

Active and passive components are formed by layers of materials with different electrical properties. The layers can be formed by a variety of deposition techniques determined in part by the type of material being deposited. For example, thin film deposition may involve chemical vapor deposition (CVD), physical vapor deposition (PVD), electrolytic plating, and electroless plating processes. Each layer is generally

patterned to form portions of active components, passive components, or electrical connections between components.

The layers can be patterned using photolithography, which involves the deposition of light sensitive material, e.g., photoresist, over the layer to be patterned. A pattern is transferred from a photomask to the photoresist using light. The portion of the photoresist pattern subjected to light is removed using a solvent, exposing portions of the underlying layer to be patterned. The remainder of the photoresist is removed, leaving behind a patterned layer. Alternatively, some types of materials are patterned by directly depositing the material into the areas or voids formed by a previous deposition/etch process using techniques such as electroless and electrolytic plating.

Depositing a thin film of material over an existing pattern can exaggerate the underlying pattern and create a non-uniformly flat surface. A uniformly flat surface is required to produce smaller and more densely packed active and passive components. Planarization can be used to remove material from the surface of the wafer and produce a uniformly flat surface. Planarization involves polishing the surface of the wafer with a polishing pad. An abrasive material and corrosive chemical are added to the surface of the wafer during polishing. The combined mechanical action of the abrasive and corrosive action of the chemical removes any irregular topography, resulting in a uniformly flat surface.

Back-end manufacturing refers to cutting or singulating the finished wafer into the individual die and then packaging the die for structural support and environmental isolation. To singulate the die, the wafer is scored and broken along non-functional regions of the wafer called saw streets or scribes. The wafer is singulated using a laser cutting tool or saw blade. After singulation, the individual die are mounted to a package substrate that includes pins or contact pads for interconnection with other system components. Contact pads formed over the semiconductor die are then connected to contact pads within the package. The electrical connections can be made with solder bumps, stud bumps, conductive paste, or wirebonds. An encapsulant or other molding material is deposited over the package to provide physical support and electrical isolation. The finished package is then inserted into an electrical system and the functionality of the semiconductor device is made available to the other system components.

FIG. 1 illustrates electronic device 50 having a chip carrier substrate or printed circuit board (PCB) 52 with a plurality of semiconductor packages mounted on its surface. Electronic device 50 may have one type of semiconductor package, or multiple types of semiconductor packages, depending on the application. The different types of semiconductor packages are shown in FIG. 1 for purposes of illustration.

Electronic device 50 may be a stand-alone system that uses the semiconductor packages to perform one or more electrical functions. Alternatively, electronic device 50 may be a sub-component of a larger system. For example, electronic device 50 may be a graphics card, network interface card, or other signal processing card that can be inserted into a computer. The semiconductor package can include microprocessors, memories, application specific integrated circuits (ASIC), logic circuits, analog circuits, RF circuits, discrete devices, or other semiconductor die or electrical components.

In FIG. 1, PCB 52 provides a general substrate for structural support and electrical interconnect of the semiconductor packages mounted on the PCB. Conductive signal traces 54 are formed over a surface or within layers of PCB 52 using evaporation, electrolytic plating, electroless plating, screen printing, or other suitable metal deposition process. Signal traces 54 provide for electrical communication between each

of the semiconductor packages, mounted components, and other external system components. Traces **54** also provide power and ground connections to each of the semiconductor packages.

In some embodiments, a semiconductor device has two packaging levels. First level packaging is a technique for mechanically and electrically attaching the semiconductor die to an intermediate carrier. Second level packaging involves mechanically and electrically attaching the intermediate carrier to the PCB. In other embodiments, a semiconductor device may only have the first level packaging where the die is mechanically and electrically mounted directly to the PCB.

For the purpose of illustration, several types of first level packaging, including wire bond package **56** and flip chip **58**, are shown on PCB **52**. Additionally, several types of second level packaging, including ball grid array (BGA) **60**, bump chip carrier (BCC) **62**, dual in-line package (DIP) **64**, land grid array (LGA) **66**, multi-chip module (MCM) **68**, quad flat non-leaded package (QFN) **70**, and quad flat package **72**, are shown mounted on PCB **52**. Depending upon the system requirements, any combination of semiconductor packages, configured with any combination of first and second level packaging styles, as well as other electronic components, can be connected to PCB **52**. In some embodiments, electronic device **50** includes a single attached semiconductor package, while other embodiments call for multiple interconnected packages. By combining one or more semiconductor packages over a single substrate, manufacturers can incorporate pre-made components into electronic devices and systems. Because the semiconductor packages include sophisticated functionality, electronic devices can be manufactured using cheaper components and a streamlined manufacturing process. The resulting devices are less likely to fail and less expensive to manufacture resulting in a lower cost for consumers.

FIGS. **2a-2c** show exemplary semiconductor packages. FIG. **2a** illustrates further detail of DIP **64** mounted on PCB **52**. Semiconductor die **74** includes an active region containing analog or digital circuits implemented as active devices, passive devices, conductive layers, and dielectric layers formed within the die and are electrically interconnected according to the electrical design of the die. For example, the circuit may include one or more transistors, diodes, inductors, capacitors, resistors, and other circuit elements formed within the active region of semiconductor die **74**. Contact pads **76** are one or more layers of conductive material, such as aluminum (Al), copper (Cu), tin (Sn), nickel (Ni), gold (Au), or silver (Ag), and are electrically connected to the circuit elements formed within semiconductor die **74**. During assembly of DIP **64**, semiconductor die **74** is mounted to an intermediate carrier **78** using a gold-silicon eutectic layer or adhesive material such as thermal epoxy or epoxy resin. The package body includes an insulative packaging material such as polymer or ceramic. Conductor leads **80** and wire bonds **82** provide electrical interconnect between semiconductor die **74** and PCB **52**. Encapsulant **84** is deposited over the package for environmental protection by preventing moisture and particles from entering the package and contaminating die **74** or wire bonds **82**.

FIG. **2b** illustrates further detail of BCC **62** mounted on PCB **52**. Semiconductor die **88** is mounted over carrier **90** using an underfill or epoxy-resin adhesive material **92**. Wire bonds **94** provide first level packaging interconnect between contact pads **96** and **98**. Molding compound or encapsulant **100** is deposited over semiconductor die **88** and wire bonds **94** to provide physical support and electrical isolation for the

device. Contact pads **102** are formed over a surface of PCB **52** using a suitable metal deposition process such as electrolytic plating or electroless plating to prevent oxidation. Contact pads **102** are electrically connected to one or more conductive signal traces **54** in PCB **52**. Bumps **104** are formed between contact pads **98** of BCC **62** and contact pads **102** of PCB **52**.

In FIG. **2c**, semiconductor die **58** is mounted face down to intermediate carrier **106** with a flip chip style first level packaging. Active region **108** of semiconductor die **58** contains analog or digital circuits implemented as active devices, passive devices, conductive layers, and dielectric layers formed according to the electrical design of the die. For example, the circuit may include one or more transistors, diodes, inductors, capacitors, resistors, and other circuit elements within active region **108**. Semiconductor die **58** is electrically and mechanically connected to carrier **106** through bumps **110**.

BGA **60** is electrically and mechanically connected to PCB **52** with a BGA style second level packaging using bumps **112**. Semiconductor die **58** is electrically connected to conductive signal traces **54** in PCB **52** through bumps **110**, signal lines **114**, and bumps **112**. A molding compound or encapsulant **116** is deposited over semiconductor die **58** and carrier **106** to provide physical support and electrical isolation for the device. The flip chip semiconductor device provides a short electrical conduction path from the active devices on semiconductor die **58** to conduction tracks on PCB **52** in order to reduce signal propagation distance, lower capacitance, and improve overall circuit performance. In another embodiment, the semiconductor die **58** can be mechanically and electrically connected directly to PCB **52** using flip chip style first level packaging without intermediate carrier **106**.

FIGS. **3a-3j** illustrate a process of forming vertically offset BOT interconnect sites on different height traces. FIG. **3a** shows a substrate **120** with a base substrate material, such as laminate BT substrate, dummy silicon wafer, germanium, gallium arsenide, indium phosphide, or silicon carbide, for structural support. Alternatively, semiconductor substrate **120** may have an active surface **122** formed over bulk material **123** containing analog or digital circuits implemented as active devices, passive devices, conductive layers, and dielectric layers electrically interconnected according to the electrical design and function of the die. For example, the circuit may include one or more transistors, diodes, and other circuit elements formed within active surface **122** to implement analog circuits or digital circuits, such as digital signal processor (DSP), ASIC, memory, or other signal processing circuit. The semiconductor substrate may also contain IPDS, such as inductors, capacitors, and resistors, for RF signal processing.

In FIG. **3b**, high-resolution dry film photoresist layer **124** is formed over active surface **122** to a thickness of 5 micrometers ( $\mu\text{m}$ ). A portion of dry film layers **124** is removed to pattern active surface **122**.

In FIG. **3c**, an electrically conductive layer **126** is formed in the removed portions of dry film layer **124** over the exposed active surface **122** using PVD, CVD, electrolytic plating, electroless plating process, or other suitable metal deposition process. Conductive layer **126** can be one or more layers of Al, Cu, Sn, Ni, Au, Ag, or other suitable electrically conductive material.

In FIG. **3d**, the remaining dry film layer **124** is removed, leaving conductive layer **126** extending above active surface **122**. In one embodiment, conductive layer **126** has a height of 5  $\mu\text{m}$  above substrate **120**.

In FIG. **3e**, high-resolution dry film photoresist layer **128** is formed over active surface **122** and conductive layer **126** to a thickness of 25  $\mu\text{m}$ . Accordingly, the thickness of dry film

layer **128** is greater than the thickness of dry film layer **124**. A portion of dry film layers **128** is removed to pattern active surface **122**.

In FIG. **3f**, an electrically conductive layer **130** is formed in the removed portions of dry film layer **128** over the exposed active surface **122** using PVD, CVD, electrolytic plating, electroless plating process, or other suitable metal deposition process. Conductive layer **130** can be one or more layers of Al, Cu, Sn, Ni, Au, Ag, or other suitable electrically conductive material.

In FIG. **3g**, the remaining dry film layer **128** is removed, leaving conductive layer **130** extending above active surface **122**. In one embodiment, conductive layer **130** has a height of 25  $\mu\text{m}$  above substrate **120**, or about 20  $\mu\text{m}$  higher than conductive layer **126**. Conductive layer **130** is formed in an alternating pattern or interposed between conductive layer **126**. That is, each conductive layer **130** is positioned adjacent to conductive layer **126**, and each conductive layer **126** is positioned adjacent to conductive layer **130**. Conductive layers **126** and **130** are placed close together to minimize pitch and increase I/O count while maintaining sufficient spacing to avoid electrical shorting after bump formation. In one embodiment, the pitch between conductive layer **126** and conductive layer **130** is less than 60  $\mu\text{m}$ .

In FIG. **3h**, a solder mask **132** is formed around conductive layers **126** and **130** in preparation for bump formation.

In FIG. **3i**, an electrically conductive bump material is deposited over conductive layer **126** using an evaporation, electrolytic plating, electroless plating, ball drop, or screen printing process. The bump material can be Al, Sn, Ni, Au, Ag, Pb, Bi, Cu, solder, and combinations thereof, with an optional flux solution. For example, the bump material can be eutectic Sn/Pb, high-lead solder, or lead-free solder. The bump material is bonded to conductive layer **126** using a suitable attachment or bonding process. In one embodiment, the bump material is reflowed by heating the material above its melting point to form spherical balls or bumps **134**. In some applications, bumps **134** are reflowed a second time to improve electrical contact to conductive layer **126**. The bumps can also be compression bonded to conductive layer **126**. Bumps **134** represent one type of interconnect structure that can be formed over conductive layer **126**. In this embodiment, bumps **134** are bond wire bumps. The interconnect structure can also use bond wires, stud bump, micro bump, or other electrical interconnect.

In FIG. **3j**, an electrically conductive bump material is deposited over conductive layer **130** using an evaporation, electrolytic plating, electroless plating, ball drop, or screen printing process. The bump material can be Al, Sn, Ni, Au, Ag, Pb, Bi, Cu, solder, and combinations thereof, with an optional flux solution. For example, the bump material can be eutectic Sn/Pb, high-lead solder, or lead-free solder. The bump material is bonded to conductive layer **130** using a suitable attachment or bonding process. In one embodiment, the bump material is reflowed by heating the material above its melting point to form spherical balls or bumps **136**. In some applications, bumps **136** are reflowed a second time to improve electrical contact to conductive layer **130**. The bumps can also be compression bonded to conductive layer **130**. Bumps **136** represent one type of interconnect structure that can be formed over conductive layer **130**. In this embodiment, bumps **136** are bond wire bumps. The interconnect structure can also use bond wires, stud bump, micro bump, or other electrical interconnect.

FIG. **4a** shows the vertical offset between bond wire bumps **134** and **136** formed on bond fingers **126** and **130**. Solder mask **132** is removed after formation of bond wire bumps **134**

and **136**. Conductive layers **126** and **130** are bond fingers formed on substrate **120**. Bond finger **126** and **130** are part of or electrically connected to traces routed on active surface **122**. The bond fingers **126** and **130** provide interconnectivity between active and passive circuits formed on active surface **122** and the external electronic components.

FIG. **4b** shows bond wires **140** are formed on bumps **134** and **136**, i.e., BOT interconnection, and routed to external electronic components. Bond wires **140** are arranged in straight-configuration to avoiding zig-zag configuration which permits use of a smaller substrate. With 20  $\mu\text{m}$  (0.8 mil) bond wires, the height of bond wire bumps **134** and **136** is about 10  $\mu\text{m}$ . The vertical offset between bond fingers **126** and **130** allows bond wire bumps to be placed closer together, e.g., smaller pitch. The outer dimensions of bond wire bumps **134** and **136** can overlap in the plan view of FIG. **4b**, but do not electrically short due to the physical separation between the bumps provided by the vertical offset, as seen in FIG. **4a**. The interconnect density of the bond wires increases with the smaller pitch of the bond wire bumps, without increasing the length of the bond fingers. In addition, the smaller pitch provides for smaller bond wires which reduces manufacturing cost.

Bond fingers **126** and **130** are formed using dual-time trace patterning, i.e., the conductive layers are formed with different trace patterning at different times, as described in FIGS. **3b-3h**. The dual-time trace patterning provides a fine pitch interconnection and enables use of smaller wafer substrate size due to straight-wire bond configuration. The substrate, bond wire, and molding compound cost are reduced.

While one or more embodiments of the present invention have been illustrated in detail, the skilled artisan will appreciate that modifications and adaptations to those embodiments may be made without departing from the scope of the present invention as set forth in the following claims.

What is claimed:

1. A method of making a semiconductor device, comprising:

- providing a substrate;
- forming a first conductive layer over the substrate;
- forming a patterned layer over the first conductive layer;
- forming a second conductive layer in the patterned layer, wherein a height of the second conductive layer is greater than a height of the first conductive layer;
- removing the patterned layer; and
- forming a first bump and a second bump over the first and second conductive layers, respectively, wherein the second bump overlaps the first bump, and wherein an uppermost surface of the second bump is vertically offset from an uppermost surface of the first bump.

2. The method of claim 1, wherein the patterned layer includes a photoresist layer.

3. The method of claim 1, further including forming bond wires on the first and second bumps.

4. The method of claim 3, wherein the bond wires are arranged in a straight configuration.

5. The method of claim 1, wherein a pitch between the first and second conductive layers is no greater than 60 micrometers.

6. The method of claim 1, further including forming a solder mask around the first and second conductive layers prior to forming the first and second bumps.

7. The method of claim 1, wherein lowermost surfaces of the first conductive layer and second conductive layer are substantially coplanar.

8. A method of making a semiconductor device, comprising:

9

providing a substrate;  
forming a plurality of first conductive layers over the substrate and including a first height;  
forming a plurality of second conductive layers over the substrate interposed between the first conductive layers and including a second height differing from the first height;  
forming a first interconnect structure over the first conductive layers and including a first upper surface; and  
forming a second interconnect structure over the second conductive layers and including a second upper surface vertically offset from the first upper surface, wherein the second interconnect structure overlaps the first interconnect structure.

**9.** The method of claim **8**, wherein forming the first interconnect structure and the second interconnect structure includes forming a conductive post or a bond wire over the first and second conductive layers.

**10.** The method of claim **8**, wherein forming the first conductive layers includes:

forming a first patterned layer over the substrate;  
forming the first conductive layers in the first patterned layer; and  
removing the first patterned layer.

**11.** The method of claim **8**, wherein forming the second conductive layers includes:

forming a second patterned layer over the substrate;  
forming the second conductive layers in the second patterned layer; and  
removing the second patterned layer.

**12.** The method of claim **8**, further including forming bond wires on the first and second interconnect structures.

**13.** The method of claim **8**, further including:  
forming the first conductive layers to a height no greater than 5 micrometers; and  
forming the second conductive layers to a height no greater than 25 micrometers.

**14.** The method of claim **8**, further including forming a solder mask around the first and second conductive layers prior to forming the first and second interconnect structures.

**15.** A method of making a semiconductor device, comprising:

providing a substrate;  
forming a plurality of first conductive layers over the substrate and including a first height;  
forming a second conductive layer between the first conductive layers and including a second height differing from the first height;  
forming a first interconnect structure over the first conductive layer and including a third height; and

10

forming a second interconnect structure over the second conductive layer and including a fourth height substantially the same as the third height.

**16.** The method of claim **15**, wherein forming the first and second interconnect structures includes:

forming first and second bumps over the first and second conductive layers, respectively; and  
forming bond wires on the first and second bumps.

**17.** The method of claim **16**, wherein an upper surface of the second bump is vertically offset from an upper surface of the first bump, and wherein a width of the first bump is substantially the same as a width of the second bump.

**18.** The method of claim **15**, wherein forming the first conductive layers includes:

forming a first patterned layer over the substrate;  
forming the first conductive layers in the first patterned layer; and  
removing the first patterned layer.

**19.** The method of claim **15**, wherein forming the second conductive layer includes:

forming a second patterned layer over the substrate;  
forming the second conductive layer in the second patterned layer; and  
removing the second patterned layer.

**20.** The method of claim **15**, further including:

forming the first conductive layers to a height no greater than 5 micrometers; and  
forming the second conductive layer to a height no greater than 25 micrometers.

**21.** The method of claim **16**, further including forming a solder mask around the first conductive layers and the second conductive layer prior to forming the first and second interconnect structures.

**22.** A semiconductor device, comprising:

a substrate;  
a first conductive layer disposed over the substrate and including a first height;  
a second conductive layer disposed over the substrate and including a second height differing from the first height;  
a first interconnect structure disposed over the first conductive layer; and  
a second interconnect structure disposed over the second conductive layer and overlapping the first interconnect structure.

**23.** The semiconductor device of claim **22**, wherein the first and second interconnect structures include conductive posts or bond wires formed over the first and second conductive layers.

**24.** The semiconductor device of claim **22**, further including a solder mask disposed around the first and second conductive layers.
