PIXEL CIRCUIT, SOLID-STATE IMAGE PICKUP DEVICE, AND CAMERA SYSTEM

RELATED APPLICATION DATA

This application is a continuation of U.S. patent application Ser. No. 13/126,790 filed Apr. 29, 2011, which is a national stage filing of PCT/JP2009/069848 filed on Nov. 25, 2009, the entireties of which are incorporated herein by reference to the extent permitted by law. The present application claims the benefit of priority to Japanese Patent Application No. JP 2008-312413 filed on Dec. 8, 2008 in the Japan Patent Office, the entirety of which is incorporated by reference herein to the extent permitted by law.

TECHNICAL FIELD

The present invention relates to a pixel circuit represented by a CMOS image sensor, a solid-state image pickup device, and a camera system.

BACKGROUND ART

Recently, CMOS imagers for a digital still camera, a camcorder, a security camera, and the like have been widely used and markets have also extended.

The CMOS imager converts light incident on each pixel into electrons by a photodiode, which is a photoelectric conversion element, accumulates the electrons for a fixed period of time, digitalizes a signal reflecting an accumulated electric charge amount thereof, and outputs the digitalized signal to the outside.

FIG. **1** is a diagram showing an example of a pixel circuit including four transistors in one unit pixel.

A pixel circuit PX**1** of one unit has a photo diode **1**, a transfer transistor **2**, a reset transistor **3**, an amplifier transistor **4**, a row selection transistor **5**, an accumulation node **6**, and floating diffusion (FD, a floating diffusion layer) **7**.

A gate electrode of the transfer transistor **2** is connected to a transfer line **8**, and a gate electrode of the reset transistor **3** is connected to a reset line **9**. A gate electrode of the amplifier transistor **4** is connected to the FD **7**, and a gate electrode of the row selection transistor **5** is connected to a row selection line **10**. A source of the row selection transistor **5** is connected to a vertical signal line **11**.

A constant current circuit **12** and a sensing circuit **13** are connected to the vertical signal line **11**.

In the pixel circuit PX**1**, light incident on a silicon substrate of a pixel generates pairs of electrons and holes, and the electrons thereof are focused and accumulated in the node **6** by the photodiode **1**. The electrons are ultimately read as a signal directed to the vertical signal line **11**.

Hereinafter, specific operations of electric charge accumulation and read will be described with reference to FIG. **2**.

FIGS. **2**(A) to **2**(D) are diagrams showing a timing chart of the pixel circuit of FIG. **1**.

First, a pixel is reset ahead of electric charge accumulation. Thereby, the reset line **9** and the transfer line **8** are set to a high level, so that the reset transistor **3** and the transfer transistor **2** are in an ON state. For example, this is an operation of transferring a power supply voltage of 3 V to the accumulation node **6** of the photodiode.

Thereby, a potential of the accumulation node **6** rises and the electrons accumulated therein are extracted.

In a hole-accumulation diode (HAD) that has recently become mainstream, the accumulation node **6** is formed in an n-type buried diffusion layer interposed between p-type layers, and all electrons are discharged, so that it is in a full depletion state. An increase of the potential of the node **6** is also stopped at a point in time when all the electrons have been discharged, and its level becomes a predetermined level lower than the power supply voltage 3 V.

Thereafter, the transfer line **8** has a low level and the transfer transistor **2** is turned off, so that the accumulation node **6** is in the floating state and new electric charge accumulation is started. During the electric charge accumulation, the reset transistor **3** is normally turned off.

In general, the above-described pixel reset operation is used as an electronic shutter operation of a CMOS image sensor.

Next, an operation of reading the accumulated electric charge will be described.

First, the row selection line **10** has a high level and the row selection transistor **5** is turned on, so that the amplifier transistor **4** of the pixel is connected to the vertical signal line **11**.

Here, the vertical signal line **11** connected to the amplifier transistor **4** and the constant current circuit **12** form a source follower circuit, and a potential Vf of the FD **7**, which is its input, and a potential Vsl of the vertical signal line **11**, which is its output, have a linear relationship close to a variation ratio of 1.

That is, if a current value of the constant current circuit **12** is i, the following expression is ideally established.

$$i=(1/2)*\beta*(Vf-Vth-Vsl)2, \quad \text{[Expression 1]}$$

where β is a constant.

Here, (Vf−Vth−Vsl) becomes constant, and a variation of Vf is linearly reflected in Vsl.

That is, the source follower circuit operates as an amplifier circuit in which a gain is about 1, and drives the vertical signal line **11** according to a signal amount of the FD **7**, which is an input node.

Here, the power supply voltage 3V is transferred to the FD **7** by switching the reset line **9** to a high level and turning on the reset transistor **3**.

Further, after the reset transistor **3** is turned off, first sensing of the potential Vsl of the vertical signal line **11** is performed by a sensing circuit **13** constituted by a comparator, an analog/digital converter (ADC), or the like. This is the read of a reset signal.

Next, electrons accumulated in the accumulation node **6** flows into the FD **7** by switching the transfer line **8** to the high level and turning on the transfer transistor **2**.

In this case, if the potential of the FD **7** is sufficiently deep, that is, a high potential, all the electrons accumulated in the accumulation node **6** are discharged to the FD **7**, and the accumulation node **6** is in the full depletion state.

Here, the transfer transistor **2** is turned off and second sensing of the potential of the vertical signal line **11** is performed. This is the read of an accumulated signal.

A difference between the first sensing and the second sensing of the above-described Vsl accurately reflects an electric charge amount accumulated in the accumulation node **6** by exposure of the photodiode **1**.

The CMOS imager digitalizes the difference and outputs the digitalized result to the outside as a pixel signal value. An electron accumulation time of each pixel is a period of time between the reset operation and the read operation described above, and accurately, is a period T**1** until the transfer transistor **2** is turned off in the read after the transfer transistor **2** is reset and then turned off.

In general, in a CMOS type imager, accumulated electrons generated by the photoelectric conversion element are converted into an analog signal of the vertical signal line **11** via

the amplifier circuit for each pixel, and the analog signal is transferred to the sensing circuit **13**.

Further, the analog signal is converted into a digital signal by the ADC, and the digital signal is output outside a chip.

This is significantly different from a CCD type imager in which accumulated electrons themselves are vertically/horizontally transferred by a CCD transfer immediately before a chip output amplifier circuit.

SUMMARY OF INVENTION

Technical Problem

Incidentally, because the photoelectrically converted electrons are completely transferred during a read operation in the above-described pixel circuit, it is necessary to maintain a potential after the transfer of the FD **7**, which is an input node of the amplifier circuit **118**, to be higher than that of the photodiode **1** during full depletion.

However, a dynamic range of the potential of the FD **7** is limited, so that there is a disadvantage in that it is not possible to sufficiently increase a potential variation amount ΔVf and increase an S/N ratio.

Further, because a saturated accumulated electric charge amount Qs of the photodiode corresponds to the number of donors within its diffusion layer, the potential during the full depletion normally becomes deep (as a high potential) if the saturated accumulated electric charge amount Qs is increased. Thereby, the range of the potential variation amount ΔVf is in a narrower direction.

A problem of this transfer margin serves as a large limitation in design.

The present invention is made in view of the above-mentioned issue, and aims to provide a pixel circuit, a solid-state image pickup device, and a camera system that can facilitate an electric charge transfer within a pixel, improve an amount of accumulated electric charge or sensitivity, and improve image pickup capability.

Solution to Problem

According to a first aspect of the present invention, there is provided a pixel circuit including: a photoelectric conversion element; an amplifier circuit; and a transfer transistor for transferring electric charge generated by the photoelectric conversion element to an input node of the amplifier circuit, wherein the transfer transistor has first, second, and third field effect transistors integrated and connected in series from the photoelectric conversion element to a side of the amplifier circuit, the first and second field effect transistors have gate electrodes to be simultaneously collectively driven, and a threshold voltage of the first field effect transistor is set to be higher than that of the second field effect transistor, and as the gate electrodes are driven step by step, the electric charge generated by the photoelectric conversion element and transferred via the first field effect transistor is accumulated in a channel region of the second field effect transistor, and the electric charge accumulated in the channel region is transferred to an input of the amplifier circuit via the third field effect transistor, and wherein the amplifier circuit drives a signal line, so that the accumulated electric charge is read.

According to a second aspect of the present invention, there is provided a pixel circuit including: a photoelectric conversion element; an amplifier circuit; and a transfer transistor for transferring electric charge generated by the photoelectric conversion element to an input node of the amplifier circuit, wherein the transfer transistor has first and second field effect transistors integrated and connected in series from the photoelectric conversion element to a side of the amplifier circuit, the first and second field effect transistors have gate electrodes to be simultaneously collectively driven, and a threshold voltage of the first field effect transistor is set to be higher than that of the second field effect transistor, and as the gate electrodes are driven step by step, a predetermined amount of electric charge generated by the photoelectric conversion element and transferred via the first field effect transistor is accumulated in a channel region of the second field effect transistor, and the electric charge accumulated in the channel region is transferred to an input of the amplifier circuit, and wherein the amplifier circuit drives a signal line, so that the accumulated electric charge is read.

According to a third aspect of the present invention, there is provided a solid-state image pickup device including: a pixel section where a plurality of pixel circuits are arranged; and a pixel driving section for reading a pixel signal by driving a pixel circuit of the pixel section, wherein each pixel circuit has: a photoelectric conversion element; an amplifier circuit; and a transfer transistor for transferring electric charge generated by the photoelectric conversion element to an input node of the amplifier circuit, wherein the transfer transistor has first, second, and third field effect transistors integrated and connected in series from the photoelectric conversion element to a side of the amplifier circuit, the first and second field effect transistors have gate electrodes to be simultaneously collectively driven, and a threshold voltage of the first field effect transistor is set to be higher than that of the second field effect transistor, and as the gate electrodes are driven by the pixel driving section step by step, the electric charge generated by the photoelectric conversion element and transferred via the first field effect transistor is accumulated in a channel region of the second field effect transistor, and the electric charge accumulated in the channel region is transferred to an input of the amplifier circuit via the third field effect transistor, and wherein the amplifier circuit drives a signal line, so that the accumulated electric charge is read.

According to a fourth aspect of the present invention, there is provided a solid-state image pickup device including: a pixel section where a plurality of pixel circuits are arranged; and a pixel driving section for reading a pixel signal by driving a pixel circuit of the pixel section, wherein each pixel circuit has: a photoelectric conversion element; an amplifier circuit; and a transfer transistor for transferring electric charge generated by the photoelectric conversion element to an input node of the amplifier circuit, wherein the transfer transistor has first and second field effect transistors integrated and connected in series from the photoelectric conversion element to a side of the amplifier circuit, the first and second field effect transistors have gate electrodes to be simultaneously collectively driven, and a threshold voltage of the first field effect transistor is set to be higher than that of the second field effect transistor, and as the gate electrodes are driven by the pixel driving section step by step, a predetermined amount of electric charge generated by the photoelectric conversion element and transferred via the first field effect transistor is accumulated in a channel region of the second field effect transistor, and the electric charge accumulated in the channel region is transferred to an input of the amplifier circuit, and wherein the amplifier circuit drives a signal line, so that the accumulated electric charge is read.

According to a fifth aspect of the present invention, there is provided a camera system including: a solid-state image pickup device; an optical system for forming an image of a subject on the image pickup device; and a signal processing circuit for processing an output image signal of the image

pickup device, wherein the solid-state image pickup device has: a pixel section where a plurality of pixel circuits are arranged; and a pixel driving section for reading a pixel signal by driving a pixel circuit of the pixel section, wherein each pixel circuit has: a photoelectric conversion element; an amplifier circuit; and a transfer transistor for transferring electric charge generated by the photoelectric conversion element to an input node of the amplifier circuit, wherein the transfer transistor has first, second, and third field effect transistors integrated and connected in series from the photoelectric conversion element to a side of the amplifier circuit, the first and second field effect transistors have gate electrodes to be simultaneously collectively driven, and a threshold voltage of the first field effect transistor is set to be higher than that of the second field effect transistor, and as the gate electrodes are driven by the pixel driving section step by step, the electric charge generated by the photoelectric conversion element and transferred via the first field effect transistor is accumulated in a channel region of the second field effect transistor, and the electric charge accumulated in the channel region is transferred to an input of the amplifier circuit via the third field effect transistor, and wherein the amplifier circuit drives a signal line, so that the accumulated electric charge is read.

According to a sixth aspect of the present invention, there is provided a camera system including: a solid-state image pickup device; an optical system for forming an image of a subject on the image pickup device; and a signal processing circuit for processing an output image signal of the image pickup device, wherein the solid-state image pickup device has: a pixel section where a plurality of pixel circuits are arranged; and a pixel driving section for reading a pixel signal by driving a pixel circuit of the pixel section, wherein each pixel circuit has: a photoelectric conversion element; an amplifier circuit; and a transfer transistor for transferring electric charge generated by the photoelectric conversion element to an input node of the amplifier circuit, wherein the transfer transistor has first and second field effect transistors integrated and connected in series from the photoelectric conversion element to a side of the amplifier circuit, the first and second field effect transistors have gate electrodes to be simultaneously collectively driven, and a threshold voltage of the first field effect transistor is set to be higher than that of the second field effect transistor, and as the gate electrodes are driven by the pixel driving section step by step, a predetermined amount of electric charge generated by the photoelectric conversion element and transferred via the first field effect transistor is accumulated in a channel region of the second field effect transistor, and the electric charge accumulated in the channel region is transferred to an input of the amplifier circuit, and wherein the amplifier circuit drives a signal line, so that the accumulated electric charge is read.

Advantageous Effects of Invention

According to the present invention, an electric charge transfer within a pixel can be facilitated, an amount of accumulated electric charge or sensitivity can be improved, and image pickup capability can be improved.

BRIEF DESCRIPTION OF DRAWINGS

FIG. **1** is a diagram showing an example of a pixel circuit.

FIG. **2** is a diagram showing a timing chart of the pixel circuit of FIG. **1**.

FIG. **3** is a diagram showing a configuration example of a CMOS image sensor (solid-state image pickup device) adopting a pixel circuit according to an embodiment of the present invention.

FIG. **4** is a diagram showing a pixel circuit of a CMOS image sensor according to a first embodiment of the present invention.

FIG. **5** is a diagram showing an equivalent circuit of a transfer circuit including a transfer transistor of the pixel circuit according to the first embodiment.

FIG. **6** is a diagram showing a cross-sectional structure example of the transfer circuit of FIG. **5**.

FIG. **7** is a diagram showing a potential change accompanying a read transfer operation using the transfer circuit of the pixel circuit according to the first embodiment.

FIG. **8** is a diagram showing a timing chart when reset, electric charge accumulation, and read operations are performed in the pixel circuit of FIG. **4**.

FIG. **9** is a diagram showing an equivalent circuit of a transfer circuit including a transfer transistor of the pixel circuit of FIG. **1**.

FIG. **10** is a diagram showing a potential change accompanying a read transfer operation using the pixel circuit as shown in FIGS. **1** and **3**.

FIG. **11** is a diagram showing a pixel circuit of a CMOS image sensor according to a second embodiment of the present invention.

FIG. **12** is a diagram showing a pixel circuit of a CMOS image sensor according to a third embodiment of the present invention.

FIG. **13** is a diagram showing a potential change accompanying a read transfer operation using the pixel circuit according to the third embodiment.

FIG. **14** is a diagram showing a timing chart when reset, electric charge accumulation, and read operations are performed in the pixel circuit of FIG. **12**.

FIG. **15** is a diagram showing a pixel circuit of a CMOS image sensor according to a fourth embodiment of the present invention.

FIG. **16** is a diagram showing a timing chart of an operation of a fifth embodiment.

FIG. **17** is a diagram showing a timing chart of an operation of a sixth embodiment.

FIG. **18** is a diagram showing a timing chart of a pixel operation adopting an intermediate retention mode and improving a large-capacity accumulation operation of the fifth embodiment in a seventh embodiment.

FIG. **19** is a diagram showing a timing chart of a pixel operation adopting an intermediate retention mode and improving a large-capacity accumulation operation of the sixth embodiment in an eighth embodiment.

FIG. **20** is a diagram showing a timing chart of an operation of a ninth embodiment in which a global shutter function is mounted in the first embodiment.

FIG. **21** is a diagram showing a timing chart of an operation of a tenth embodiment in which a global shutter function is mounted in the third embodiment.

FIG. **22** is a first potential change diagram illustrating an example of a wide dynamic timing range operation of an eleventh embodiment using a configuration of the first embodiment.

FIG. **23** is a second potential change diagram illustrating an example of a wide dynamic range operation of the eleventh embodiment using the configuration of the first embodiment.

FIG. **24** is a diagram showing a timing chart of a wide dynamic range correspondence operation according to the eleventh embodiment.

FIG. **25** is a diagram showing a timing chart of a wide dynamic range operation of a twelfth embodiment using a configuration of the third embodiment.

FIG. **26** is a diagram showing a pixel circuit of a CMOS image sensor according to a thirteenth embodiment of the present invention.

FIG. **27** is a diagram showing an equivalent circuit of a transfer circuit including a transfer transistor of a pixel circuit according to the thirteenth embodiment.

FIG. **28** is a diagram showing a cross-sectional structure example of the transfer circuit of FIG. **27**.

FIG. **29** is a diagram showing a potential change accompanying a read transfer operation using a transfer circuit of the pixel circuit according to the thirteenth embodiment.

FIG. **30** is a diagram showing a pixel circuit of a CMOS imager according to a fourteenth embodiment of the present invention.

FIG. **31** is a diagram showing a configuration example of a transfer circuit according to a fifteenth embodiment in which a photodiode is replaced with a MOS capacitor with respect to FIG. **6**, which is the cross-sectional structure example corresponding to the first embodiment.

FIG. **32** is a diagram showing a cross-sectional structure example of a transfer circuit according to a sixteenth embodiment having a cross-sectional structure different from the transfer circuit of the first embodiment.

FIG. **33** is a diagram showing an example of a configuration of a camera system to which a solid-state image pickup device is applied according to an embodiment of the present invention.

DESCRIPTION OF EMBODIMENTS

Hereinafter, preferred embodiments of the present invention will be described in detail with reference to the appended drawings. Note that, in this specification and the drawings, elements that have substantially the same function and structure are denoted with the same reference signs, and repeated explanation is omitted.

Description will be given in the following order.

1. First Embodiment (First Configuration Example of Pixel Circuit)
2. Second Embodiment (Second Configuration Example of Pixel Circuit)
3. Third Embodiment (Third Configuration Example of Pixel Circuit)
4. Fourth Embodiment (Fourth Configuration Example of Pixel Circuit)
5. Fifth Embodiment (Electric Charge Accumulation Example Using Deep Depletion State)
6. Sixth Embodiment (Electric Charge Accumulation Example Using Deep Depletion State)
7. Seventh Embodiment (Intermediate Retention Mode)
8. Eighth Embodiment (Intermediate Retention Mode)
9. Ninth Embodiment (Global Shutter Function)
10. Tenth Embodiment (Global Shutter Function)
11. Eleventh Embodiment (Wide Dynamic Range Operation)
12. Twelfth Embodiment (Wide Dynamic Range Operation)
13. Thirteenth Embodiment (Fifth Configuration Example of Pixel Circuit)
14. Fourteenth Embodiment (Sixth Configuration Example of Pixel Circuit)
15. Fifteenth Embodiment (Another Cross-sectional Structure)
16. Sixteenth Embodiment (Another Cross-sectional Structure)
17. Seventeenth Embodiment (Camera System)

FIG. **3** is a diagram showing a configuration example of a CMOS image sensor (solid-state image pickup device) adopting a pixel circuit according to an embodiment of the present invention.

A CMOS image sensor **100** has a pixel array section **110**, a row selection circuit (Vdec) **120** as a pixel driving section, and a column read circuit (AFE) **130**.

In the pixel array section **110**, a plurality of pixel circuits **110**A are arranged in a two-dimensional form (matrix form) of M rows×N columns.

According to this embodiment, the pixel circuit **110**A basically includes a photoelectric conversion element, a transfer transistor, a reset transistor, an amplifier transistor, a row selection transistor, an accumulation node, and FD (floating diffusion).

In this regard, the transfer transistor of the pixel circuit **110**A is formed of at least first and second insulating gate type field effect transistors (MOS transistors) integrated and connected in series as described later. The first and second MOS transistors are formed of a transistor of a high threshold voltage Vth and a transistor of a low threshold voltage Vth having gate electrodes to be simultaneously collectively driven.

A specific configuration of the pixel circuit **110**A will be described later.

A transfer line **140** (LTRG), a reset line **150** (LRST), and a row selection line **160** (LSL) wired to the pixel array section **110** are wired in each row unit of a pixel arrangement as one set.

M control lines are provided for each of the transfer line **140** (LTRG), the reset line **150** (LRST), and the row selection line **160** (LSL).

The transfer line **140** (LTRG), the reset line **150** (LRST), and the row selection line **160** (LSL) are driven by the row selection circuit **120**.

The row selection circuit **120** controls an operation of a pixel arranged in any row of the pixel array section **110**. The row selection circuit **120** controls the pixel circuit through the transfer line **140** (LTRG), the reset line **150** (LRST), and the row selection line **160** (LSL).

The column read circuit **130** receives data of a pixel row in which a read operation is under control of the row selection circuit **120** via a vertical signal line (LSGN) **170**, and transfers the data to a rear-stage signal processing circuit. A constant current circuit or a sensing circuit is connected to the vertical signal line **170**.

The column read circuit **130** includes a CDS circuit or an ADC (analog-digital converter).

Hereinafter, a specific configuration example of the pixel circuit of the CMOS image sensor **100** having the configuration as described above will be described.

1. First Embodiment

FIG. **4** is a diagram showing a pixel circuit of a CMOS image sensor according to a first embodiment of the present invention.

The pixel circuit **110**A (PX**111**) of one unit has a photodiode **111** as a photoelectric conversion element, a transfer transistor **112**, a reset transistor **113**, an amplifier transistor **114**, a row selection transistor **115**, an accumulation node **116**, and FD **117**.

An amplifier circuit **118** is formed of the amplifier transistor **114**, and an input node of the amplifier circuit **118** is formed of the FD **117**.

The transfer transistor **112** of the first embodiment is connected between the photodiode **111** and the FD **117** as an output node.

The transfer transistor **112** is formed of at least a first MOS transistor **1121**, a second MOS transistor **1122**, and a third MOS transistor **1123** integrated and connected in series.

The first and second MOS transistors **1121** and **1122** are formed of a transistor of a high threshold voltage Vth and a transistor of a low threshold voltage Vth having gate electrodes to be driven by a driving signal simultaneously collectively applied.

The first MOS transistor **1121** is formed of a transistor of a high threshold voltage HVth, and the second MOS transistor **1122** is formed of a transistor of a low threshold voltage LVth.

The gate electrodes of the first and second MOS transistors **1121** and **1122** are commonly connected to the transfer line **140**, and a gate electrode of the third MOS transistor **1123** is connected to a reference potential, for example, a ground GND.

In this embodiment, the first, second, and third MOS transistors **1121**, **1122**, and **1123** are formed of n-channel MOS (NMOS) transistors.

For example, the high threshold voltage HVth of the first NMOS transistor **1121** is set, for example, to 0 V, and the low threshold voltage LVth of the second NMOS transistor **1122** is set, for example, to −1.5 V.

A threshold voltage of the third NMOS transistor is set to −0.6 V.

The reset transistor **113** is connected between a power supply line and the FD **117**, and its gate electrode is connected to the reset line **150**.

A gate of the amplifier transistor **114** is connected to the FD **117**. The amplifier transistor **114** is connected to the vertical signal line **170** via the row selection transistor **115**, and constitutes a source follower with a constant current circuit **131** outside a pixel section.

A gate electrode of the row selection transistor **115** is connected to the row selection line **160**. A source of the row selection transistor **115** is connected to the vertical signal line **170**.

The constant current circuit **131** and a sensing circuit **132** are connected to the vertical signal line **170**.

FIG. **5** is a diagram showing an equivalent circuit of a transfer circuit including the transfer transistor of the pixel circuit **110**A according to the first embodiment.

In a transfer circuit **200** of FIG. **5**, reference numerals **201** and **202** denote gate electrodes, reference numeral **203** denotes parasitic capacitance, and reference numeral **118** denotes the amplifier circuit. The amplifier circuit **118** is formed of the amplifier transistor **114**.

Electrons generated by photoelectric conversion in the photodiode **111** are completely transferred to the FD **117**, which is the input node of the amplifier circuit **118**, via the first, second, and third NMOS transistors **1121**, **1122**, and **1123** integrated and connected in series.

In the integrated first, second, and third NMOS transistors **1121**, **1122**, and **1123**, channels are directly connected to each other, not via an n-type diffusion layer or the like.

As described above, a driving signal is simultaneously collectively applied to gate electrodes **201** of the first and second NMOS transistors **1121** and **1122**.

The first MOS transistor **1121** has the high threshold voltage HVth, and the second MOS transistor **1122** has the low threshold voltage LVth.

The FD **117**, which is the input node, has the parasitic capacitance **203**, and its potential variation amount ΔVf is as follows if an accumulated electric charge amount is Q and a parasitic capacitance value is Cf.

$$\Delta Vf = Q/Cf \quad \text{[Expression 2]}$$

During a read operation, this displacement drives the vertical signal line **170** at a fixed gain via the amplifier circuit **118**.

FIG. **6** is a diagram showing a cross-sectional structure example of the transfer circuit of FIG. **5**.

In the photodiode **111**, a HAD structure in which the vicinity of a silicon surface in contact with an oxide film has a p-type is adopted.

Here, the photoelectrically converted electrons are initially accumulated in an n-type diffusion node **204**. The diffusion node **204** corresponds to the accumulation node **116**.

If a signal that turns on the first NMOS transistor **1121** is applied to the gate electrode **201**, the electrons are transferred to a channel region of the second NMOS transistor **1122** via the first NMOS transistor **1121**, and accumulated in the channel region.

For example, an impurity profile of a channel portion is adjusted, so that a threshold of the first NMOS transistor **1121** is set to be high and a threshold of the second NMOS transistor **1122** is set to be low. Thereby, a channel portion CH**2** of the second NMOS transistor **1122** forms an electron accumulation well, and a channel portion CH**1** of the first NMOS transistor **1121** forms a potential wall of backflow prevention.

On the other hand, the third NMOS transistor **1123** is controlled by an independent gate electrode **202**.

A potential of a channel region of the third NMOS transistor **1123** is set to be shallower than that of the second NMOS transistor **1122** (as a high potential) when an ON voltage is applied to the gate electrode **201**.

The potential of the channel region is set to be deeper than that of the second NMOS transistor **1122** (as a low potential) when an OFF voltage is applied to the gate electrode **201**.

The gate electrode **202** of the third NMOS transistor **1123** may have a fixed potential, and may also be connected to a power supply line, a ground line, or the like if an impurity profile of a channel portion CH**3** of the third NMOS transistor **1123**, or the like is appropriately adjusted.

A diffusion layer **205** is connected to an input of the amplifier circuit **118**, which is not shown in the cross-sectional view.

The third NMOS transistor **1123** functions as a separation transistor.

Here, the first NMOS transistor **1121** and the second NMOS transistor **1122** are considered two individual transistors. However, they may also be considered a single NMOS transistor having a gradient in the impurity profile of the channel portion if the gate electrodes are also integrally formed as shown in the figure.

In any case, it is functionally the same as two individual transistors connected in series. The present invention also includes the above-described form.

FIGS. **7**(A) to **7**(D) are diagrams showing potential changes accompanying a read transfer operation using the transfer circuit of the pixel circuit according to the first embodiment.

In terms of the potential of each node in FIGS. **7**(A) to **7**(D), a positive potential direction is shown on the lower side in the figure and a negative potential direction is shown on the upper side. Each node serves a well where electrons having negative electric charge are accumulated, and the potential rises to the upper side, that is, in the negative potential direction, with the well filled with the electrons.

[Step T11]

In step ST11 of FIG. 7(A), the diffusion node 204 of the photodiode 111 is designed so that a potential bottom is about 2.0 V during full depletion in positive electric charge by a fixed number of donors. Here, it is filled with photoelectrically converted electrons up to a saturation state (about 0 V).

On the other hand, in the channel regions of the first NMOS transistor 1121 and the second NMOS transistor 1122, potentials are respectively modulated in ranges of R11 and R12 according to a potential commonly applied to the gate electrodes of the two, for example, −1.5 V to 3 V.

On the other hand, the gate electrode 202 of the third NMOS transistor 1123 as the separation transistor is connected to the ground GND, and the potential of the channel is adjusted to about 0.6 V.

The diffusion layer 205 (the FD 117), which is the input node of the amplifier circuit 118, is reset to have a floating state of 3 V.

[Step ST12]

If the first NMOS transistor 1121 and the second NMOS transistor 1122 are turned on in step ST12 of FIG. 7(B), electrons move as follows.

Electrons accumulated in the diffusion node 204 of the photodiode 111 all move to the channel region of the second NMOS transistor 1122 via the first NMOS transistor 1121.

That is, the electrons move to the channel region of the second NMOS transistor 1122 having a deep depletion state and are accumulated in an analog state.

At this time, the potential of the channel region of the third NMOS transistor 1123 is shallower than that of the second NMOS transistor 1122 (as a low potential), and forms a barrier between the second NMOS transistor 1122 and the diffusion layer 205 (the FD 117), which is the input node of the amplifier circuit 118.

[Step ST13]

The gate electrodes are driven to turn off the first NMOS transistor 1121 and the second NMOS transistor 1122 in step ST13 of FIG. 7(C), so that the potentials of the channel regions are modulated in the negative potential direction.

Here, the channel of the first NMOS transistor 1121 forms a potential barrier, and prevents accumulated electrons from flowing back to the diffusion node 204 of the photodiode 111.

A height of the barrier corresponds to a difference between thresholds of two transistors of the first NMOS transistor 1121 and the second NMOS transistor 1122, for example, 1.5 V.

In the step in which the gate electrodes 201 of the first and second NMOS transistors 1121 and 1122 have reached an appropriate intermediate voltage, a state in which the accumulated electrons have been separated from both the diffusion node 204 of the photodiode 111 and the FD 117, which is the input of the amplifier, is possible.

The gates may be directly driven at once until the next step, but it is also possible to add a new function by temporarily retaining this intermediate state as will be described later.

Further, if the potential of the channel region of the second NMOS transistor 1122 is modulated in the negative potential direction by continuously driving the gate from here, the electrons accumulated therein start to move to the diffusion layer 205 (the FD 117), which is the input of the amplifier circuit 118.

[Step ST14]

If the first NMOS transistor 1121 and the second NMOS transistor 1122 are completely turned off in step ST14 of FIG. 7(D), the potential of the channel region of the second NMOS transistor 1122 from which all accumulated electrons have been discharged is as follows.

That is, the potential of the channel region of the second NMOS transistor 1122 exceeds the potential of the channel of the third NMOS transistor 1123.

In step ST11, a state is reached in which all electrons accumulated in the photodiode 111 have moved to the diffusion layer 205 (the FD 117), which is the input node of the amplifier circuit 118.

Thereby, the amplifier circuit 118 drives the vertical signal line 170, and an accumulated signal is read.

If the above-described step-by-step transfer is used, it is unnecessary to secure a potential difference between the diffusion node 204 of the photodiode 111 having the full depletion state and the FD 117, which is the input node of the amplifier circuit 118.

That is, in this example, a complete transfer is implemented even in a state in which the potential of the FD 117 filled with electrons is shallower than that of the diffusion node 204.

The operation of the transfer circuit of the pixel circuit 110A according to the first embodiment has been mainly described above.

Next, electric charge accumulation and read operations of the pixel circuit 110A of the first embodiment will be described.

FIGS. 8(A) to 8(D) are diagrams showing a timing chart when reset, electric charge accumulation, and read operations are performed in the pixel circuit of FIG. 4.

FIG. 8(A) shows a signal potential of the reset line 150, FIG. 8(B) shows a signal potential of the transfer line 140, FIG. 8(C) shows a signal potential of the row selection line 160, and FIG. 8(D) shows a signal potential of the vertical signal line 170.

As a characteristic operation of the pixel circuit 110A of the first embodiment, the transfer of accumulated electrons of the photodiode 111 to the FD 117 is performed in two steps in correspondence with driving of the transfer line 140.

That is, if a level of the transfer line 140 rises from the low level to the high level, the accumulated electrons are transferred from the diffusion node 204 of the photodiode 111 to the channel region of the second NMOS transistor 1122 as shown in step ST12 of FIG. 7(B).

Further, when the level of the transfer line 140 returns from the high level to the low level, the electrons of the channel region are transferred to the FD 117, which is the input node of the amplifier circuit 118, as shown in step ST14 of FIG. 7(D).

For example, the reset line 150 has the high level during reset, so that the FD 117, which is the input node of the amplifier circuit 118, is connected to a reset level potential (power supply voltage 3V).

On the other hand, at a point in time when the level of the transfer line 140 has risen from the low level to the high level and has further fallen from the high level to the low level, the electrons accumulated in the photodiode 111 are transferred to the diffusion layer 205 and drawn to the reset level.

At this point in time, a new electron accumulation period T2 starts.

A reset pulse of the reset line 150 falls to the low level after waiting for the level of the transfer line 140 to fall to the low level.

Likewise, during a read operation also, the electrons accumulated in the photodiode 111 are transferred to the diffusion layer 205 at a point in time when the level of the transfer line 140 has risen from the low level to the high level and further fallen from the high level to the low level.

Therefore, the vertical signal line 170 is driven by the accumulated signal via the amplifier circuit 118 at a point in time when the level of the transfer line 140 has returned from

the high level to the low level. At this point in time, the accumulation period T**2** also ends.

The pixel circuit **110**A according to the above-described first embodiment can facilitate an electric charge transfer within a pixel of a CMOS image sensor, improve an accumulated electric charge amount or sensitivity, and improve image pickup capability.

Here, processing of a transfer circuit system of the pixel circuit of FIG. **1** for a comparison with the pixel circuit **110**A according to the above-described first embodiment will be described.

FIG. **9** is a diagram showing an equivalent circuit of the transfer circuit including the transfer transistor of the pixel circuit PX**1** of FIG. **1**.

In the transfer circuit TX**1** of FIG. **9**, GT**1** denotes a gate electrode, C**1** denotes parasitic capacitance, and reference numeral **14** denotes the amplifier circuit. The amplifier circuit **14** is formed of the amplifier transistor **4**.

In the transfer circuit TX**1**, electrons generated by photoelectric conversion in the photodiode **1** are accumulated in the accumulation node **6**, which is a diffusion layer node of the photodiode **1**.

During a read operation, the electrons are completely transferred to the FD **7**, which is the input node of the amplifier circuit **14**, via the transfer transistor **2**.

If the FD **7**, which is the input node, has the parasitic capacitance C**1**, an accumulated electric charge amount is Q, and a parasitic capacitance value is Cf, its potential variation amount ΔVf is given as $\{\Delta Vf=Q/Cf\}$ as described above.

The amplifier circuit **14** uses an NMOS transistor like the normal amplifier transistor **4**, but generates unique random noise Nr.

Therefore, if its gain is G, an S/N ratio of an accumulated signal occurring in the vertical signal line as an output is $\{G\cdot\Delta Vf/Nr\}$.

Because the gain G or the random noise Nr are substantially fixed if the configuration of the amplifier circuit **14** is decided, the magnitude of the potential variation amount ΔVf directly affects image pickup performance.

FIGS. **10**(A) to **10**(D) are diagrams showing potential changes accompanying a read transfer operation using the pixel circuit as shown in FIGS. **1** and **3**.

As in FIGS. **7**(A) to **7**(D), in this case also, in terms of the potential of each node, a positive potential direction is shown on the lower side in the figure and a negative potential direction is shown on the upper side.

Each node serves a well where electrons having negative electric charge are accumulated, and the potential rises to the upper side, that is, in the negative potential direction, with the well filled with the electrons.

[Step ST**1**]

In step ST**1** of FIG. **10**(A), the accumulation node **6**, which is the diffusion node of the photodiode **1**, is designed so that a potential bottom is about 1.5 V during full depletion in positive electric charge by a fixed number of donors. Here, it is filled with photoelectrically converted electrons up to a saturation state (about 0 V).

On the other hand, the channel region of the transfer transistor **2** is modulated in a range of R**1** according to a potential applied to the gate electrode, for example, 1 V to 3 V.

The FD **7**, which is the input node of the amplifier circuit **14**, is reset to have a floating state of 3 V.

[Step ST**2**]

If the transfer transistor **2** is turned on in step ST**2** of FIG. **10**(B), electrons move as follows.

That is, if the transfer transistor **2** is turned on, the electrons move in a state in which all the electrons accumulated in the accumulation node **6**, which is the diffusion node of the photodiode **1**, have been distributed to the channel region of the transfer transistor **2** and the FD **7**, which is the input node of the amplifier circuit **14**.

[Step ST**3**]

If the potential of the channel region rises with a potential increase in the gate electrode in order to turn off the transfer transistor **2** in step ST**3** of FIG. **10**(C), the electrons accumulated therein move to the FD **7**, which is the input node of the amplifier circuit **14**.

[Step ST**4**]

In step ST**4** of FIG. **10**(D), a state is reached in which all electrons accumulated in the photodiode **1** in step ST**1** have moved to the FD **7**, which is the input node of the amplifier circuit **14**, in a state in which the transfer transistor **2** has been turned off. Thereby, the amplifier circuit **14** drives the vertical signal line **11**, and an accumulated signal is read.

As described above, it is necessary for the pixel circuit PX**1** of FIG. **1** to secure a potential difference Ml between the accumulation node **6** of the photodiode **1** having a full depletion state and the FD **7**, which is the input node of the amplifier circuit **14**, in order to implement complete electron movement.

On the other hand, if the potential difference is not sufficiently secured, the electrons accumulated in the channel region of the transfer transistor **2** flow back to the photodiode **1**, and an accumulated electron amount of the photodiode **1** is not linearly reflected in a read signal.

In order to completely transfer electrons photoelectrically converted during a read operation as described above, it is necessary to maintain the potential after the transfer of the FD **7**, which is the input node of the amplifier circuit **14**, as a potential higher than that of the photodiode **1** during full depletion.

However, the pixel circuit PX**1** of FIG. **1** has a disadvantage in that a dynamic range of the potential of the FD **7** is limited, ΔVf cannot be sufficiently increased, and the S/N ratio cannot be increased.

For example, in FIG. **10**, ΔVf has a limit of (3.0 V−1.5 V), and is further reduced by a potential difference of a transfer margin.

Further, because a saturated accumulated electric charge amount Qs of the photodiode **1** corresponds to the number of donors within its diffusion layer, the potential during the full depletion becomes deep (as a high potential) if Qs is normally increased. Thereby, a range of ΔVf is in a narrower direction.

A problem of this transfer margin serves as a large limitation in design.

On the other hand, the pixel circuit **110**A of the first embodiment adopts a transfer by integrated series transistors for the transfer of electrons from the photodiode within the pixel to the amplifier circuit. Specifically, in the pixel circuit **110**A, an intermediate transfer node in which potential modulation is possible is formed in a channel portion of a MOS transistor, and accumulated electrons are transferred step by step from the photodiode **111** to the amplifier circuit **118** via the intermediate node.

Therefore, the pixel circuit **110**A of the first embodiment can release the above-described potential limitation for the transfer, and hence improve a dynamic range of a signal by increasing the saturated accumulated electric charge amount Qs or reducing parasitic capacitance of an amplifier input portion.

Further, for example, the pixel circuit **110**A can accumulate electrons photoelectrically converted during exposure in the channel region of the MOS transistor separately formed, not within the photodiode, and completely transfer the accu-

mulated electrons from the channel region to the amplifier circuit during a read operation.

Therefore, the pixel circuit **110**A can improve exposure sensitivity and also significantly improve the saturated accumulated electric charge amount Qs.

In the pixel circuit **110**A, an electron (electric charge) transfer is performed only inside the pixel, and an analog signal of low impedance or a digital signal is transferred after driving of the vertical signal line by the amplifier circuit.

Therefore, it is possible to implement a high-speed, low-power consumption imager without a problem of M smear or transfer leak.

2. Second Embodiment

FIG. **11** is a diagram showing a pixel circuit of a CMOS image sensor according to a second embodiment of the present invention.

A difference between a pixel circuit **110**B according to the second embodiment and the pixel circuit **110**A according to the first embodiment is as follows.

In the pixel circuit **110**B according to the second embodiment, a plurality of pixels, for example, two pixels PXL**110***a* and PXL**110***b*, respectively having a unique photodiode **111** and a unique transfer circuit **112**, share FD **117** and an amplifier transistor **114** forming an amplifier circuit.

In the pixel circuit **110**B, the plurality of pixels PXL**110***a* and PXL**110***b* also share a reset transistor **113** and a row selection transistor **115**.

In transfer transistors **112***a* and **112***b* of the respective pixels PXL**110***a* and PXL**110***b*, shared gate electrodes of first and second NMOS transistors are respectively connected to different transfer lines **140***a* and **140***b*.

Incidentally, gate electrodes of third MOS transistors **1123** of the transfer transistors **112***a* and **112***b* of the respective pixels PXL**110***a* and PXL**110***b* are respectively grounded.

In the pixel circuit **110**B, electrons accumulated in respective photodiodes **111***a* and **111***b* are transferred to the FD**117** (an input node of the amplifier circuit) at individual timings according to the respectively independent transfer lines **140***a* and **140***b*.

The sharing of the amplifier circuit can reduce an effective size of the pixel, but parasitic capacitance of the FD **117** also increases when the number of sharing pixels increases.

Therefore, it is preferable that the number of sharing pixels be equal to or greater than 2 and equal to or less than 16.

The second embodiment can have the same advantageous effects as the above-described first embodiment.

3. Third Embodiment

FIG. **12** is a diagram showing a pixel circuit of a CMOS image sensor according to a third embodiment of the present invention.

A difference between a pixel circuit **110**C according to the third embodiment and the pixel circuit **110**A according to the first embodiment is as follows.

In the pixel circuit **110**C of the third embodiment, a gate electrode **202** of a third NMOS transistor **1123**, which has a fixed potential in the first embodiment, is subsidiarily driven by a row selection circuit **120**, which is a peripheral circuit.

Specifically, a shared gate electrode **201** of first and second NMOS transistors **1121** and **1122** is connected to a first transfer line **141**, and the gate electrode **202** of the third NMOS transistor **1123** is connected to a second transfer line (separation line) **142**.

Thereby, as the transfer via the third NMOS transistor **1123** can be facilitated, a driving range at the side of the gate electrode **201** can be narrowed.

While there is a disadvantage in an area when the number of driving wirings is increased by 1, there is an advantage in voltage resistance or reliability when the driving range of the first transfer line **141** can be narrowed.

FIGS. **13**(A) to **13**(D) are diagrams showing potential changes accompanying the read transfer operation using the pixel circuit **110**C according to the third embodiment.

[Step ST**21**]

In step ST**21** of FIG. **13**(A), a diffusion node **204** of a photodiode **111** is designed so that a potential bottom is about 2.0 V during full depletion in positive electric charge by a fixed number of donors. Here, it is filled with photoelectrically converted electrons up to a saturation state (about 0 V).

On the other hand, in channel regions of the first NMOS transistor **1121** and the second NMOS transistor **1122**, potentials are respectively modulated in ranges of R**13** and R**14** according to a potential commonly applied to gate electrodes of the two, for example, −0.5 V to 3 V.

On the other hand, in a channel region of the third NMOS transistor **1123** as a separation transistor, a potential uniquely applied to its gate electrode is modulated in a range of R**15**, for example, according to 0 V to 3 V.

A diffusion layer **205** (FD **117**), which is an input node of an amplifier circuit **118**, is reset to have a floating state of 3 V.

[Step ST**22**]

If the first NMOS transistor **1121** and the second NMOS transistor **1122** are turned on in step ST**22** of FIG. **13**(B), an electron transfer is performed as follows.

That is, electrons accumulated in the diffusion node **204** of the photodiode **111** all move to the channel region of the second NMOS transistor **1122** via the first NMOS transistor **1121**.

That is, the electrons move to the channel region of the second NMOS transistor **1122** having a deep depletion state and are accumulated in an analog state.

At this time, the potential of the channel region of the third NMOS transistor **1123** is shallower than that of the second NMOS transistor **1122** (as a low potential), and forms a barrier between the second NMOS transistor **1122** and the diffusion layer **205** (the FD **117**), which is the input node of the amplifier circuit **118**.

[Step ST**23**]

If the first NMOS transistor **1121** and the second NMOS transistor **1122** are turned off again in step ST**23** of FIG. **13**(C), the potentials of the channel regions are modulated in the negative potential direction.

Here, a channel of the first NMOS transistor **1121** forms a potential barrier, and prevents accumulated electrons from flowing back to the diffusion node **204** of the photodiode **111**.

A height of the barrier corresponds to a difference between thresholds of two transistors of the first NMOS transistor **1121** and the second NMOS transistor **1122**, for example, 1.5 V.

In this step, a state in which the accumulated electrons have been separated from both the diffusion node **204** of the photodiode **111** and the diffusion layer **205** (the FD **117**), which is the input of the amplifier circuit **118**, is possible.

It may proceed to the next step at once by directly or simultaneously driving the gate of the third NMOS transistor **1123**, but it is also possible to add a new function by temporarily retaining this intermediate state as will be described later.

[Step ST24]

If the gate electrode 202 of the third NMOS transistor 1123 is driven through the second transfer line 142 as the separation line in step ST24 of FIG. 13(D) and the third NMOS transistor 1123 is turned on, the accumulated electrons flow into the FD 117, which is the input node of the amplifier circuit 118.

Further, at a point in time when the third NMOS transistor 1123 has been turned off, a state is reached in which all the accumulated electrons have moved to the diffusion layer 205 (the FD 117), which is the input node of the amplifier circuit 118.

Thereby, the amplifier drives the vertical signal line and an accumulated signal is read.

As described above, the transfer from the channel of the second NMOS transistor 1122 to the FD 117, which is the input node of the amplifier circuit 118, in the third embodiment is performed as follows.

It is implemented by combining both OFF driving of the shared gate electrode 201 of the first and second NMOS transistors 1121 and 1122 of step ST23 and auxiliary ON/OFF driving of the gate electrode 202 of the third NMOS transistor 1123 of step ST24.

If the above-described step-by-step transfer is used, it is unnecessary to secure a potential difference between the diffusion node 204 of the photodiode 111 having the full depletion state and the FD 117, which is the input node of the amplifier circuit 118.

That is, in this example, a complete transfer is implemented even in a state in which the potential of the FD 117 filled with electrons is shallower than that of the diffusion node 204.

The transfer operation of the pixel circuit 110C according to the third embodiment has been mainly described above.

Next, electric charge accumulation and read operations of the pixel circuit 110C of the third embodiment will be described.

FIGS. 14(A) to 14(E) are diagrams showing a timing chart when the reset, electric charge accumulation, and read operations are performed in the pixel circuit of FIG. 12.

FIG. 14(A) shows a signal potential of a reset line 150, FIG. 14(B) shows a signal potential of the first transfer line 141, and FIG. 14(C) shows a signal potential of the second transfer line 142. FIG. 14(D) shows a signal potential of a row selection line 160, and FIG. 14(E) shows a signal potential of a vertical signal line 170.

A main difference in the operation between the third embodiment and the first embodiment shown in FIG. 8 is as follows.

In the third embodiment, an ON/OFF pulse of the second transfer line 142, which drives the third NMOS transistor 1123, is added to assist the transfer of accumulated electrons when the first and second NMOS transistors 1121 and 1122 are turned off by the first transfer line 141.

That is, if a level of the first transfer line 141 rises from the low level to the high level, the accumulated electrons are transferred from the diffusion node 204 of the photodiode 111 to the channel region of the second NMOS transistor 1122 as shown in step ST22 of FIG. 13(B).

Further, if the level of the first transfer line 141 returns from the high level to the low level and the second transfer line 142 as the separation line has the high level at substantially the same time, the electrons move as follows.

As shown in step ST24 of FIG. 13(D), the third NMOS transistor 1123 as the separation transistor is conductive and the accumulated electrons flow into the FD 117, which is the input node of the amplifier circuit 118.

Ultimately, if the level of the second transfer line 142 as the separation line falls to the low level, a complete transfer of electrons to the FD 117, which is the input node of the amplifier circuit 118, is completed.

For example, the reset line 150 has the high level during reset, so that the FD 117, which is the input node of the amplifier circuit, is connected to a reset level potential (power supply voltage 3 V).

On the other hand, the level of the first transfer line 141 rises from the low level to the high level, so that extra electrons accumulated in the photodiode 111 are transferred to a channel portion CH2 of the second NMOS transistor 1122 via the first NMOS transistor 1121.

Further, the level of the first transfer line 141 falls from the high level to the low level and the second transfer line 142 as the separation line has the high level at substantially the same time, so that the third NMOS transistor 1123, which is the separation transistor, is conductive.

Ultimately, if the level of the second transfer line 142 as the separation line falls to the low level, the accumulated electrons are completely transferred to the FD 117 and drawn to the reset level.

At this point in time, a new electron accumulation period T3 starts. More precisely, T3 starts at a point in time when the level of the first transfer line 141 has fallen from the high level to the low level.

Likewise, the level of the first transfer line 141 first rises from the low level to the high level during a read operation also, so that the electrons accumulated in the photodiode 111 are transferred to the channel portion of the second MOS transistor 1122 via the first NMOS transistor 1121.

Further, if the level of the first transfer line 141 falls from the high level to the low level and the level of the second transfer line 142 as the separation line rises to the high level at substantially the same time and further ultimately falls to the low level, the electrons are completely transferred to the FD 117, which is the input node of the amplifier circuit 118.

At this point in time, the accumulation period T3 ends.

The timing that the second transfer line 142 as the separation line is turned on at the high level may be before/after the timing that the first transfer line 141 is turned off at the low level.

If the amplifier transistor 114 has been turned on through the FD 117 before the first transfer line 141 has an OFF level, it moves to step ST14 of FIG. 13(D) by skipping the states of step ST22 of FIG. 13(B) to step ST23 of FIG. 13(C).

However, a complete transfer can be implemented if the second transfer line 142 as the separation line has the OFF level after the first transfer line 141 has the OFF level.

The third embodiment can improve voltage resistance or reliability in addition to the advantageous effects of the first embodiment.

4. Fourth Embodiment

FIG. 15 is a diagram showing a pixel circuit of a CMOS image sensor according to a fourth embodiment of the present invention.

A difference between a pixel circuit 110D according to the fourth embodiment and the pixel circuit 110C according to the third embodiment is as follows.

In the pixel circuit 110D according to the fourth embodiment, a plurality of pixels, for example, two pixels PXL110*a* and PXL110*b*, respectively having a unique photodiode 111 and a unique transfer circuit 112, share FD 117 and an amplifier transistor 114 forming an amplifier circuit.

In the pixel circuit **110**D, the plurality of pixels PXL**110***a* and PXL**110***b* also share a reset transistor **113** and a row selection transistor **115**.

In transfer transistors **112***a* and **112***b* of the respective pixels PXL**110***a* and PXL**110***b*, shared gate electrodes of first and second NMOS transistors are respectively connected to different first transfer lines **141***a* and **141***b*.

Gate electrodes of third MOS transistors **1123** of the transfer transistors **112***a* and **112***b* of the respective pixels PXL**110***a* and PXL**110***b* are respectively connected to second transfer lines **142***a* and **142***b* as separation lines.

In the pixel circuit **110**D, electrons accumulated in respective photodiodes **111***a* and **111***b* are transferred to the FDF **117** at individual timings according to the respectively independent first transfer lines **141***a* and **141***b* and the second transfer lines **142***a* and **142***b* as the separation lines.

The sharing of the amplifier circuit can reduce an effective size of the pixel, but parasitic capacitance of the FD **117** also increases when the number of sharing pixels increases.

Therefore, it is preferable that the number of sharing pixels be equal to or greater than 2 and equal to or less than 16.

The fourth embodiment can have the same advantageous effects as the above-described first embodiment.

Next, an application operation, which makes it possible to perform large-capacity accumulation by utilizing the configuration of the pixel circuit according to the embodiment of the present invention, will be described.

The large-capacity accumulation operation is applicable to any circuit configuration of the above-described first to fourth embodiments, and will be described below as fifth and sixth embodiments.

5. Fifth Embodiment

In a fifth embodiment of the present invention, electric charge accumulation is applied using the pixel circuit configuration of FIG. **4** and the deep depletion state of the second NMOS transistor **1122** adopted in the first embodiment.

Specifically, electrons accumulated in the diffusion node **204**, which is the diffusion layer of the photodiode **111**, are transferred to the channel portion of the second NMOS transistor **1122** and accumulated in the channel portion during an accumulation period.

That is, during the accumulation period of a pixel, the gate electrode **201** is maintained at a level of an ON state so that the first and second NMOS transistors **1121** and **1122** are maintained in the ON state.

Electrons photoelectrically converted by the photodiode **111** are directly transferred to the channel portion CH**2** of the second NMOS transistor **1122** via the first NMOS transistor **1121**, and accumulated in the channel portion CH**2**.

At a point in time when accumulation is completed and read is performed, the gate electrode **201** is driven to turn off the first and second NMOS transistors **1121** and **1122**. Thereby, the accumulated electrons are transferred to the FD **117**, which is the input node of the amplifier circuit **118**, via the third NMOS transistor **1123**.

FIGS. **16**(A) to **16**(D) are diagrams showing a timing chart of an operation of the fifth embodiment.

FIG. **16**(A) shows a signal potential of the reset line **150**, FIG. **16**(B) shows a signal potential of the transfer line **140**, FIG. **16**(C) shows a signal potential of the row selection line **160**, and FIG. **16**(D) shows a signal potential of the vertical signal line **170**.

In the fifth embodiment, a pixel circuit is the same as shown in FIG. **4**, and details and a cross-sectional configuration of a transfer circuit are the same as shown in FIGS. **5** and **6**.

The same reset as in FIGS. **8**(A) to **8**(D) is performed. After new accumulation starts, the transfer line **140** has the high-level state again, and is maintained in the high-level state during an accumulation period T**4**.

During this period, electrons photoelectrically converted by the photodiode **111** are not accumulated within the diffusion layer, but are directly transferred to the channel region of the second NMOS transistor **1122** and accumulated in the channel region.

During a read operation, first, the row selection line **160** has the high level, and an output of the amplifier circuit is connected to the vertical signal line **170**.

Further, the FD **117**, which is the input node of the amplifier circuit **118**, is reset by a pulse directed to the reset line **150**, and the FD **117** is connected to a power supply voltage source, so that the reset level is read.

Next, the transfer line **140** has a transition from the high level to the low level.

Thereby, the electrons accumulated in the channel region of the second NMOS transistor **1122** are transferred to the FD **117**, which is the input node of the amplifier circuit **118**, and an accumulated signal is read.

The accumulation period T**4** also ends with the transition of the transfer line **140**.

A potential change of this embodiment is based on FIGS. **7**(A) to **7**(D), but the duration of electron accumulation has the state of step ST**12** of FIG. **7**(B), not step ST**11** of FIG. **7**(A).

In the accumulation period, the first NMOS transistor **1121** and the second NMOS transistor **1122** are maintained in the ON state. Then, electrons photoelectrically converted by the photodiode **111** and collected in the diffusion node **204** directly move to the channel region of the second NMOS transistor **1122** via the first NMOS transistor **1121**.

That is, the electrons move to the channel region of the second NMOS transistor **1122** having the deep depletion state, and are accumulated in an analog state.

The transfer of electrons from the second NMOS transistor **1122** to the diffusion layer **205** during a read operation is the same as the process of steps ST**13** and ST**14** of FIGS. **7**(C) and **7**(D).

As described above, during the accumulation period, the electrons photoelectrically converted in the state of step ST**12** of FIG. **7**(B) are all accumulated in the channel region of the second NMOS transistor **1122**, and there is no saturation until its potential well is full.

Therefore, it is possible to accumulate a larger number of electrons than in accumulation directed to a normal photodiode if accumulation capacity is sufficiently increased in the deep depletion state of the second NMOS transistor **1122**.

Further, during this period, the photodiode **111** is constantly maintained in the same full depletion state. Therefore, sensitivity or linearity of an accumulation time and an accumulated signal is improved.

In general, in terms of electron/hole pairs generated by light incidence directed to a photodiode, holes generated inside a depletion layer are drawn by its internal electric field and rapidly discharged to a substrate.

However, if electrons are accumulated inside the photodiode, the internal electric field is mitigated, hole discharge capability is reduced, and electrons and holes are easily recombined.

Thereby, there is a problem in that sensitivity is gradually reduced.

On the other hand, this problem does not occur in the fifth embodiment.

Because there is no problem even when a saturated accumulated electric charge amount of the photodiode itself is little, it is possible to suppress a dark current or white spot from occurring by reducing an impurity concentration of the diffusion layer.

In this case, the potential formed in the diffusion node **204** of the photodiode **111** can be shallow during reset. Therefore, the modulation ranges R**11** and R**12** of the channel regions of the first NMOS transistor **1121** and the second NMOS transistor **1122** can also be decreased and securement of reliability of voltage resistance or the like is facilitated.

As described above, it is possible to improve all basic performances of an image pickup device for an accumulated electric charge amount, sensitivity, and a white spot.

6. Sixth Embodiment

A sixth embodiment in which the same concept is applied to the third embodiment will be described.

FIG. **17**(A) shows a signal potential of the reset line **150**, FIG. **17**(B) shows a signal potential of the first transfer line **141**, and FIG. **17**(C) shows a signal potential of the second transfer line (separation line) **142**. FIG. **17**(D) shows a signal potential of the row selection line **160**, and FIG. **17**(E) shows a signal potential of the vertical signal line **170**.

In the sixth embodiment, a pixel circuit is the same as that of FIG. **12**, and a potential change of the transfer is based on FIGS. **13**(A) to **13**(D).

The same reset as in FIGS. **14**(A) to **14**(E) is performed. After new accumulation starts, the first transfer line **141** is in the high-level state again, and is maintained in the high-level state during an accumulation period T**5**.

During this period, electrons photoelectrically converted by the photodiode **111** are not accumulated within the diffusion layer, but are directly transferred to the channel region of the second NMOS transistor **1122** and accumulated in the channel region.

That is, the state of step ST**22** of FIG. **13**(B) of the potential diagrams is retained.

During a read operation, first, the row selection line **160** has the high level, and an output of the amplifier circuit **118** is connected to the vertical signal line **170**.

Further, the FD **117**, which is the input node of the amplifier circuit **118**, is reset by a pulse directed to the reset line **150**, and the FD **117** is connected to a power supply voltage source, so that a reset level is read.

Next, the first transfer line **141** has a transition from the high level to the low level, and further a pulse is also applied to the second transfer line **142** as the separation line.

Thereby, electrons accumulated in the channel region of the second NMOS transistor **1122** are transferred to the FD **117**, which is the input node of the amplifier circuit **118**, and an accumulated signal is read.

The accumulation period T**5** also ends with the transition of the first transfer line **141**.

As described above, during the accumulation period, the electrons photoelectrically converted in the state of step ST**22** of FIG. **13**(B) are all accumulated in the channel region of the second NMOS transistor **1122**, and there is no saturation until its potential well is full.

Therefore, it is possible to accumulate a larger number of electrons than in accumulation directed to a normal photodiode if accumulation capacity is sufficiently increased in the deep depletion state of the second NMOS transistor **1122**.

Incidentally, the intermediate state of step ST**13** in the potential change of FIG. **7** showing the first embodiment is as follows.

Electrons accumulated in the channel region of the second NMOS transistor **1122**, which is the intermediate accumulation node, are separated from the FD **117**, which is in the amplifier input, as well as from the diffusion node **204** of the photodiode **111**.

That is, electrons newly photoelectrically converted in the diffusion node **204** of the photodiode **111** do not flow into the intermediate accumulation node and electrons accumulated in the intermediate accumulation node do not flow into the FD **117**.

In the first embodiment, the shared gate of the first and second NMOS transistors **1121** and **1122** is driven in three values, and the above-described state is implemented at its intermediate voltage, so that the intermediate state can be retained during a fixed period.

Likewise, the potential change of FIG. **13** showing the second embodiment in the intermediate state of step ST**23** is as follows.

The electrons accumulated in the channel region of the second NMOS transistor **1122**, which is the intermediate accumulation node, are separated from the FD **117**, which is in the amplifier input, as well as from the diffusion node **204** of the photodiode **111**.

In this case, it is possible to retain the intermediate state during a fixed period by turning off all the first and second NMOS transistors **1121** and **1122** and the third NMOS transistor **1123** by a gate electrode driving operation.

Various additional functions can be implemented if accumulated electrons received from the photodiode **111** are kept during a fixed period in the intermediate accumulation node in which potential modulation is possible.

More specifically, the fixed period is, for example, a period equal to or greater than a minimum accumulation period, or a period equal to or greater than a period taken to read one row.

Hereinafter, three functions of large-capacity accumulation, a global shutter, and a wide dynamic range will be sequentially described in seventh to fourteenth embodiments.

All of the seventh to twelfth embodiments can be equally performed using each configuration of the above-described first to fourth embodiments.

7. Seventh Embodiment

FIGS. **18**(A) to **18**(D) are diagrams showing a timing chart of a pixel operation adopting the above-described intermediate retention mode and improving the large-capacity accumulation operation of the fifth embodiment in a seventh embodiment.

FIG. **18**(A) shows a signal potential of the reset line **150**, FIG. **18**(B) shows a signal potential of the transfer line **140**, FIG. **18**(C) shows a signal potential of the row selection line **160**, and FIG. **18**(D) shows a signal potential of the vertical signal line **170**.

In the seventh embodiment, a pixel circuit is the same as shown in FIG. **4**, and details and a cross-sectional configuration of a transfer circuit are the same as shown in FIGS. **5** and **6**.

If the first and second NMOS transistors **1121** and **1122** are continuously opened via the gate electrode **201**, there is a tendency for a potential of the photodiode **111** of FIG. **6** around the gate to rise and a dark current to increase.

In view of the above-described problem, the seventh embodiment, which is an improved example, suppresses the dark current from being increased by driving the gate electrode **201** and intermittently turning on the first and second NMOS transistors **1121** and **1122**.

That is, first, new accumulation is started by performing the same reset operation as that of FIG. **8** or **16**. Thereafter, during an accumulation period T**6**, electrons are transferred from the photodiode **111** to the intermediate accumulation node by time division by causing the first and second NMOS transistors **1121** and **1122** to intermittently have the high level without being continuously opened via the gate electrode **201**.

During the accumulation period other than a transfer time after an initial transfer, the gate electrode **201** is kept at the intermediate potential, and the intermediate state of step ST**13** of FIG. **7**(C) is maintained in the intermediate accumulation node.

The gate electrode **201** has the high level again during a read operation, and electrons remaining in the photodiode **111** are transferred to the intermediate accumulation node. Ultimately, the gate electrode **201** has the low level, and accumulated electrons of the intermediate accumulation node are together collectively transferred to the FD **117**, which is the amplifier input.

Normally, because all photoelectrically converted electrons are accumulated in the photodiode **111** after the reset operation, its saturated accumulated electric charge amount Qs decides a dynamic range of a pixel.

However, if the accumulation capacity of the intermediate accumulation node having the channel portion of the second NMOS transistor **1122** is sufficiently large, it is possible to accumulate a larger amount of electric charge than normal by transferring the accumulated electric charge of the photodiode **111** to the intermediate accumulation node a plurality of times by time division.

Because a period in which the first and second NMOS transistors **1121** and **1122** are turned on through the gate electrode **201** can be sufficiently reduced as compared to the accumulation period, it is also possible to prevent a dark current from being increased.

8. Eighth Embodiment

FIGS. **19**(A) to **19**(E) are diagrams showing a timing chart of a pixel operation adopting the same intermediate retention mode as that of the seventh embodiment and improving the large-capacity accumulation operation of the sixth embodiment in an eighth embodiment.

FIG. **19**(A) shows a signal potential of the reset line **150**, FIG. **19**(B) shows a signal potential of the first transfer line **141**, and FIG. **19**(C) shows a signal potential of the second transfer line (separation line) **142**. FIG. **19**(D) shows a signal potential of the row selection line **160**, and FIG. **19**(E) shows a signal potential of the vertical signal line **170**.

In the eighth embodiment, a pixel circuit is the same as that of FIG. **12**, and a potential change of the transfer is based on FIGS. **13**(A) to **13**(D).

In the eighth embodiment, which is an improved example, new accumulation is started by performing the same reset as that of FIG. **14** or **17**.

Thereafter, during an accumulation period T**7**, electrons are transferred from the photodiode **111** to the intermediate accumulation node by time division by intermittently applying a pulse without continuously opening the first and second NMOS transistors **1121** and **1122** by driving of the gate electrode **201**.

During the accumulation period, the third NMOS transistor **1123** is maintained in the OFF state through the separation gate electrode **202**, and the intermediate accumulation node is maintained in the intermediate state of step ST**23** of FIG. **13**(C) other than the above-described intermittent transmission time.

The pulse is applied to the gate electrode **201** again during a read operation, and the first and second NMOS transistors **1121** and **1122** are turned on, and thus electrons remaining in the photodiode **111** are transferred to the intermediate accumulation node.

Ultimately, the pulse is applied to the separation gate electrode **202**, the third NMOS transistor **1123** is turned on, and the accumulated electrons of the intermediate accumulation node are together collectively transferred to the FD **117**, which is the amplifier input.

Like the seventh embodiment, the eighth embodiment can suppress a dark current from being increased while implementing large-capacity accumulation.

[Global Shutter Function]

Next, the global shutter function will be described.

The global shutter function is a function of removing focal plane distortion generated by the variation of a shutter timing within a pixel array.

If a normal circuit configuration and sequence are adopted, the start of the read operation decides an accumulation end timing as shown in FIG. **2**.

Because the read is normally sequentially performed for each row, the accumulation end timing also follows it. Consequently, normally, the reset operation serving as the accumulation start also varies for each row and is sequentially performed, and the accumulation period T**1** is taken uniformly in all effective pixels.

This is a general method in a CMOS image sensor called a rolling shutter, and means that the shutter timing varies for each row. For example, distortion occurs in an image of a subject operating at high speed.

On the other hand, the global shutter function is implemented by simultaneously collectively starting electric charge accumulations of all the effective pixels and further simultaneously collectively terminating the accumulations.

On the other hand, in this case, because accumulated data is read for each row, it is necessary to separate the accumulation end timing and the read timing, and it is necessary to store a signal for each pixel during a period from the accumulation end to the read.

If the configuration of the transfer circuit shown in FIG. **5** is used and its intermediate retention mode is used, the above-described operation and good signal storage are possible.

That is, in the CMOS image sensor **100**, the first and second NMOS transistors **1121** and **1122** are simultaneously turned off through the gate electrode **201** with respect to all the effective pixels. Thereby, the accumulation is terminated by stopping the transfer of photoelectrically converted electrons, and also already accumulated electrons are stored once in the channel region of the second NMOS transistor **1122**.

Thereafter, it is preferable to sequentially turn on the third NMOS transistor **1123** by applying a pulse to the gate electrode **202** with the read in units of rows and transfer stored electrons to the FD **117**, which is the input node of the amplifier circuit **118**.

9. Ninth Embodiment

FIGS. **20**(A) to **20**(D) are diagrams showing a timing chart of the operation of a ninth embodiment in which the global shutter function is mounted in the first embodiment.

FIG. **20**(A) shows a signal potential of the reset line **150**, FIG. **20**(B) shows a signal potential of the transfer line **140**, FIG. **20**(C) shows a signal potential of the row selection line **160**, and FIG. **20**(D) shows a signal potential of the vertical signal line **170**.

In the ninth embodiment, the pixel circuit is based on FIG. **4**, and the potential change is based on FIG. **7**.

The reset line **150** has the high level during reset, so that the FD **117**, which is the input node of the amplifier circuit **118**, is connected to a reset level (power supply voltage 3 V).

On the other hand, at a point in time when the level of the transfer line **140** has risen from the low level to the high level and has further fallen from the high level to the low level, electrons accumulated in the photodiode **111** are transferred to the FD **117** and drawn to the reset level.

At this point in time, a new electron accumulation period T**8** starts. A pulse of the reset line **150** falls to the low level after waiting for a pulse applied to the gate electrode **201** to fall to the low level.

Normally, this reset operation is sequentially performed for each selected row, but the global reset is performed for all the effective pixels at the same time.

That is, this process serves as a shutter opening operation of the global shutter.

At an accumulation end time when a predetermined accumulation time T**8** has elapsed, first, the level of the transfer line **140** rises from the low level to the high level, so that electrons accumulated in the photodiode **111** are transferred to the intermediate accumulation node. At this time, a potential state corresponds to step ST**12** of FIG. **7**(B).

Further, if the transfer line **140** returns from the high level to the intermediate potential, the potential state moves to the intermediate retention mode of step ST**13** of FIG. **7**(B) and the intermediate accumulation node and the photodiode **111** are separated.

These are simultaneously performed for all the effective pixels, and serve as a shutter closing operation of the global shutter.

The read is sequentially performed for each row according to a row address.

First, after a selection signal is applied to the row selection line **160** and row selection is selectively performed, a pulse is applied to the reset line **150**, the FD **117**, which is an amplifier input section, is connected to a reset level, and the reset level is sensed.

Next, the level of the transfer line **140** falls from the intermediate potential to the low level, so that all electrons retained in the intermediate accumulation node are transferred to the FD **117**, which is the input node of the amplifier circuit **118**.

Each pixel maintains the intermediate retention mode during a period of H**8** from the accumulation end to the read, but the intermediate retention period H**8** is different for each row.

That is, the above-described intermediate retention is performed during a period until it has a turn to read a corresponding row after the shutter is closed at once.

10. Tenth Embodiment

FIGS. **21**(A) to **21**(E) are diagrams showing a timing chart of the operation of a tenth embodiment in which the global shutter function is mounted in the third embodiment.

FIG. **21**(A) shows a signal potential of the reset line **150**, FIG. **21**(B) shows a signal potential of the first transfer line **141**, and FIG. **21**(C) shows a signal potential of the second transfer line (separation line) **142**. FIG. **21**(D) shows a signal potential of the row selection line **160**, and FIG. **21**(E) shows a signal potential of the vertical signal line **170**.

In the tenth embodiment, a pixel circuit is the same as that of FIG. **12**, and a potential change of the transfer is based on FIGS. **13**(A) to **13**(D).

The reset line **150** has the high level during reset, so that the FD **117**, which is the input node of the amplifier circuit **118**, is connected to a reset level (power supply voltage 3 V).

On the other hand, the level of the first transfer line **141** rises from the low level to the high level, so that extra electrons accumulated in the photodiode **111** are transferred to the channel portion of the second NMOS transistor **1122** via the first NMOS transistor **1121**.

Further, the level of the first transfer line **141** falls from the high level to the low level and the second transfer line **142** as the separation line has the high level at substantially the same time, so that the third NMOS transistor **1123** for separation is conductive. Ultimately, if the level of the second transfer line **142** falls to the low level, the accumulated electrons are completely transferred to the diffusion layer **205** and drawn to the reset level.

At this point in time, a new electron accumulation period T**9** starts. Normally, this reset operation is sequentially performed for each selected row, but the global reset is performed for all effective pixels at the same time.

That is, this process serves as a shutter opening operation of the global shutter.

At an accumulation end time when a predetermined accumulation time T**9** has elapsed, first, the level of the first transfer line **141** rises from the low level to the high level, so that electrons accumulated in the photodiode **111** are transferred to the intermediate accumulation node. At this time, a potential state corresponds to step ST**22** of FIG. **13**(B).

Further, if the first transfer line **141** returns from the high level to the low level, the potential state moves to the intermediate retention mode of step ST**23** of FIG. **13**(B) and the intermediate accumulation node and the photodiode are separated.

These are simultaneously performed for all the effective pixels, and serve as a shutter closing operation of the global shutter.

The read is sequentially performed for each row according to a row address.

First, after a selection signal is applied to the row selection line **160** and row selection is selectively performed, a pulse is applied to the reset line **150**, the FD **117**, which is the input node of the amplifier circuit **118**, is connected to a reset level, and the reset level is sensed.

Next, the second transfer line **142** as the separation line is driven to the high level, and the third NMOS transistor **1123**, which is the separation transistor, is conductive. Thereby, electrons accumulated in the channel portion of the second NMOS transistor **1122** are transferred to the FD **117**, which is the input node of the amplifier **118**.

At a point in time when the second transfer line **142** as the separation line has fallen again to the low level, the complete transfer of accumulated electrons to the diffusion layer **205** is completed.

Each pixel maintains the intermediate retention mode during a period of H**9** from the accumulation end to the read, but the intermediate retention period H**9** is different for each row.

That is, the above-described intermediate retention is performed during a period until it has a turn to read a corresponding row after the shutter is closed at once.

The global shutter function can also be performed in combination with the above-described large-capacity accumulation operation.

For example, when the accumulation of a global shutter sequence shown in FIGS. **20**(A) to **20**(D) is started, transfer lines **140** of all effective pixels are collectively changed to the high level. It is preferable to terminate the accumulation by collectively dropping them to the intermediate potential after

maintaining their state during the accumulation period T**8** and move to the intermediate retention state.

In this case, the potential state of step ST**12** of FIG. **7**(B) is maintained in each pixel during the accumulation period, and electrons are accumulated within the channel of the second NMOS transistor **1122**, not in the photodiode **111**, so that large-capacity accumulation is possible.

Likewise, a combination with a large-capacity accumulation operation by a time division transfer is also possible, and the large-capacity accumulation operation and the global shutter function can be combined and used along with a basic function of the first embodiment and a basic configuration of the third embodiment.

[Wide Dynamic Range Function]

Next, the wide dynamic range function will be described.

This function is a function of simultaneously storing a signal of a short accumulation time and a signal of a long accumulation time and picking up an image in an exposure time simultaneously appropriate for the two signals using the signal of the short accumulation time for sensing a subject of high luminance and the signal of the long accumulation time for sensing a subject of low luminance.

If the configuration of the first or third embodiment of the present invention and the intermediate retention mode are applied, it is possible to accumulate a separate signal in the photodiode while storing a signal accumulated for a long time in the channel region of the transistor in the intermediate retention mode.

During a read operation, the signal of the long-time accumulation side stored in the intermediate retention mode is first transferred to the amplifier input, and then the signal of the short-time accumulation side stored in the photodiode is transferred.

11. Eleventh Embodiment

An example of the wide dynamic range operation using the configuration of the first embodiment will be described using potential changes of FIGS. **22**(A) to **22**(D) and FIGS. **23**(A) to **23**(C).

FIGS. **22**(A) to **22**(D) are first potential change diagrams illustrating an example of the wide dynamic range operation according to an eleventh embodiment using the configuration of the first embodiment.

FIGS. **23**(A) to **23**(C) are second potential change diagrams illustrating an example of the wide dynamic range operation according to the eleventh embodiment using the configuration of the first embodiment.

In the eleventh embodiment, a pixel circuit is the same as shown in FIG. **4**, details and a cross-sectional configuration of a transfer circuit are the same as shown in FIGS. **5** and **6**.

[Step ST**31**]

In step ST**31** of FIG. **22**(A) like step ST**11** of FIG. **7**(A), first electron accumulation is performed in the diffusion node **204** of the photodiode **111**.

In the channel regions of the first NMOS transistor **1121** and the second NMOS transistor **1122**, potentials are respectively modulated in ranges of R**11** and R**12** according to a potential commonly applied to the shared gate electrode **201** of the two, for example, −1.5 to 3 V.

On the other hand, the gate electrode **202** of the third NMOS transistor **1123**, which is the separation transistor, is connected to the ground GND, and the potential of the channel is adjusted to about 0.6 V.

[Step ST**32**]

If the first NMOS transistor **1121** and the second NMOS transistor **1122** are turned on in step ST**32** of FIG. **22**(B), the electrons move.

Electrons accumulated in the diffusion node **204** of the photodiode **111** all move to the channel region of the second NMOS transistor **1122** via the first NMOS transistor **1121**.

That is, the electrons move to the channel region of the second NMOS transistor **1122** having a deep depletion state and are accumulated in an analog state.

[Step ST**33**]

The gate electrode **201** is driven to turn off the first NMOS transistor **1121** and the second NMOS transistor **1122** in step ST**33** of FIG. **22**(C), so that the potential of the channel region is modulated in the negative potential direction.

Thereby, the photodiode **111** is separated from the channel of the second NMOS transistor **1122**, and first accumulation is completed.

In the step in which the gate electrodes of the first NMOS transistor **1121** and the second NMOS transistor **1122** have reached an appropriate intermediate voltage, a state is reached in which the accumulated electrons have been separated from both the photodiode **111** and the FD **117**, which is the input node of the amplifier circuit **118**.

[Step ST**34**]

Because light is continuously incident on the photodiode **111** and photoelectrically converted if the intermediate retention state of step ST**33** is maintained in step ST**34** of FIG. **22**(D), new electrons are accumulated in its diffusion node **204**.

[Step ST**35**]

If the first NMOS transistor **1121** and the second NMOS transistor **1122** are completely turned off in step ST**35** of FIG. **23**(A), the electrons move as follows.

That is, all first accumulated electrons retained in the channel of the second NMOS transistor **1122** move to the FD **117**, which is the input node of the amplifier circuit **118**.

Thereby, the amplifier circuit **118** having the amplifier transistor **114** drives the vertical signal line **170**, and a first accumulated signal is read.

[Step ST**36**]

If the first NMOS transistor **1121** and the second NMOS transistor **1122** are turned on again in step ST**36** of FIG. **23**(B), the electrons move as follows.

Second accumulated electrons accumulated in the diffusion node **204** of the photodiode **111** all move to the channel region of the second NMOS transistor via the first NMOS transistor **1121**. At this time, the FD **117**, which is the input node of the amplifier circuit **118**, is reset to 3 V.

[Step ST**37**]

If the first NMOS transistor **1121** and the second NMOS transistor **1122** are completely turned off again in step ST**37** of FIG. **23**(C), the electrons move as follows.

All of the second accumulated electrons retained in the channel of the second NMOS transistor **1122** move to the FD **117**, which is the input node of the amplifier circuit.

Thereby, the amplifier circuit **118** having the amplifier transistor **114** drives the vertical signal line **170**, and a second accumulated signal is read.

By adjusting an effective timing of the above-described operation sequence, the first electron accumulation is performed for a long time and the second electron accumulation is performed for a short time.

If the first electron accumulation is not saturated, its value is used in accumulated data of a pixel. On the other hand, if the first electron accumulation is saturated, a value of the second electron accumulation is used in the accumulated data of the

pixel. If the second accumulation time is 1/K of the first accumulation time, second accumulated data is handled to be K times during image synthesis.

The long-time accumulation and the short-time accumulation are continuously performed without the read in the middle. The read is sequentially continuously performed twice for each row.

Therefore, frame synthesis is possible if a user of an imager according to the embodiment of the present invention prepares only two line buffers without having to prepare two frame buffers corresponding to different accumulation times.

When the read time is doubled, a frame rate becomes ½ but all the doubled time taken for one frame can be used in accumulation.

FIGS. **24**(A) to **24**(D) are diagrams showing a timing chart of the above-described wide dynamic range correspondence operation.

FIG. **24**(A) shows a signal potential of the reset line **150**, FIG. **24**(B) shows a signal potential of the transfer line **140**, FIG. **24**(C) shows a signal potential of the row selection line **160**, and FIG. **24**(D) shows a signal potential of the vertical signal line **170**.

First, the reset line **150** is set to the high level during reset, so that the FD **117**, which is the input node of the amplifier circuit **118**, is connected to a reset level (power supply voltage 3 V).

On the other hand, at a point in time when the level of the transfer line **140** has risen from the low level to the high level and has further fallen from the high level to the low level, electrons accumulated in the photodiode **111** are transferred to the FD **117** and drawn to the reset level.

At this point in time, an accumulation period T**10**L of the first electron accumulation starts. A pulse of the reset line **150** falls to the low level after waiting for the level of the transfer line **140** to fall to the low level.

When a predetermined accumulation time has elapsed, the level of a transfer line rises from the low level to the high level, and accumulated electrons are transferred to the intermediate node formed in the channel portion of the second NMOS transistor **1122** as shown in step ST**32** of FIG. **22**(B).

Further, if the level of the transfer line **140** falls from the high level to the intermediate potential, the photodiode **11** and the intermediate node are disconnected as shown in step ST**33** of FIG. **22**(C), and the accumulation period T**10**L of the long-time side of the first electron accumulation ends.

Simultaneously, a second accumulation period T**10**S starts.

After a selection signal is applied to the row selection line **160** and row selection is performed, the read is performed as follows.

First, the FD **117**, which is the input node of the amplifier circuit **118**, is reset by a pulse application of the reset line **150**, and the reset level is sensed.

Next, if the level of the transfer line **140** falls to the low level from the intermediate node, the first accumulated electrons are transferred to the FD **117**, which is the input node of the amplifier circuit **118**, as shown in step ST**35** of FIG. **23**(A), and their sensing is performed.

The FD **117**, which is the input node of the amplifier circuit **118**, is reset again by a pulse application of the reset line **150**, and the reset level is sensed.

Next, if the pulse is applied to the transfer line **140**, the second accumulated signal is transferred to the FD **117**, which is the input node of the amplifier circuit **118**, through steps ST**36** and ST**37** of FIGS. **23**(B) and **23**(C), and its sensing is performed.

The accumulation period T**10**S also ends by reading the second accumulated signal.

12. Twelfth Embodiment

The above-described wide dynamic range function is also performed with the same concept for the configuration of the third embodiment.

FIGS. **25**(A) to **25**(E) are diagrams showing a timing chart of the wide dynamic range operation according to a twelfth embodiment using the configuration of the third embodiment.

In the twelfth embodiment, a configuration of a pixel configuration is the same as that of FIG. **12**.

The reset line **150** has the high level during reset, so that the FD **117**, which is the input node of the amplifier circuit **118**, is connected to a reset level (power supply voltage 3 V).

On the other hand, the level of the first transfer line **141** rises from the low level to the high level, so that extra electrons accumulated in the photodiode **111** are transferred to the channel portion of the second NMOS transistor **1122** via the first NMOS transistor **1121**.

Further, the level of the first transfer line **141** falls from the high level to the low level and the second transfer line **142** as the separation line has the high level at substantially the same time, so that the third NMOS transistor **1123**, which is the separation transistor, is conductive. Ultimately, if the level of the second transfer line **142** falls to the low level, accumulated electrons are completely transferred to the FD **117** and drawn to the reset level.

At this point in time, an accumulation period T**11**L of the first electron accumulation starts. A pulse of the reset line **150** falls to the low level after waiting for the level of the second transfer line **142** to fall to the low level.

If a predetermined accumulation time has elapsed, the level of the first transfer line **141** rises from the low level to the high level, so that electrons accumulated in the photodiode **111** are transferred to the intermediate accumulation node.

Further, if the first transfer line **141** returns from the high level to the low level, the potential state moves to the intermediate retention mode of step ST**23** of FIG. **13**(B) and the intermediate accumulation node and the photodiode are separated.

Thereby, the accumulation period T**11**L of the long-time side of the first electron accumulation ends. Simultaneously, a second accumulation period T**11**S starts.

After a selection signal is applied to the row selection line **160** and row selection is performed, the read is performed as follows.

First, a pulse is applied to the reset line **150**, the FD **117**, which is the input node of the amplifier circuit **118**, is connected to the reset level, and the reset level is sensed.

Next, the second transfer line **142** as the separation line is driven to the high level, and the third NMOS transistor **1123** as the separation transistor is conductive. Thereby, the first accumulated electrons accumulated in the channel portion of the second NMOS transistor **1122** are transferred to the FD **117**, which is the input node of the amplifier circuit **118**. At a point in time when the second transfer line **142** as the separation line has fallen again to the low level, the complete transfer of the first accumulated electrons to the FD **117** is completed and the first accumulated signal is sensed.

The FD **117**, which is the input node of the amplifier circuit **118**, is reset again by a pulse application of the reset line **150**, and the reset level is sensed.

Next, the first transfer line **141** is driven from the low level to the high level, so that the second accumulated electrons accumulated in the photodiode **111** are transferred to the channel portion of the second NMOS transistor **1122** via the first NMOS transistor **1121**.

Further, if the level of the first transfer line **141** falls from the high level to the low level, the second transfer line **142** as the separation line has the high level at substantially the same time, and ultimately the level of the second transfer line **142** falls to the low level, the second accumulated electrons are completely transferred to the FD **117**.

Thereby, the second accumulation period T**11**S also ends, and the second accumulated signal is subsequently sensed.

If the first electron accumulation is not saturated, its value is used in accumulated data of a pixel. On the other hand, if the first electron accumulation is saturated, a value of the second electron accumulation is used in the accumulated data of the pixel. If the second accumulation time is 1/K of the first accumulation time, second accumulated data is handled to be K times during image synthesis.

13. Thirteenth Embodiment

Next, the twelfth embodiment in which the structure of a transfer circuit within a pixel is changed will be described.

FIG. **26** is a diagram showing a pixel circuit of a CMOS image sensor according to a thirteenth embodiment of the present invention.

A pixel circuit **110**E according to the thirteenth embodiment has a configuration in which the third NMOS transistor **1123** as the separation transistor of the transfer transistor **112** of the pixel circuit **110**A according to the first embodiment is omitted.

That is, in the pixel circuit **110**E according to the thirteenth embodiment, a transfer transistor **112**E is formed of the first MOS transistor **1121** of the high threshold voltage HVth, and the second MOS transistor **1122** of the low threshold voltage LVth integrated and connected in series.

FIG. **27** is a diagram showing an equivalent circuit of the transfer circuit including the transfer transistor of the pixel circuit **110**E according to the thirteenth embodiment.

Electrons generated by photoelectric conversion in the photodiode **111** are completely transferred to the FD **117**, which is the input node of the amplifier circuit **118**, via the first and second NMOS transistors **1121** and **1122** integrated and connected in series to form the transfer transistor **112**E.

In the integrated first and second NMOS transistors **1121** and **1122**, channels are directly connected to each other, not via an n-type diffusion layer or the like.

A driving signal is collectively applied to the gate electrodes **201** of the first and second NMOS transistors **1121** and **1122** at the same time.

The first NMOS transistor **1121** has the high threshold voltage HVth, and the second NMOS transistor **1122** has the low threshold voltage LVth.

The FD **117**, which is the input node, has the parasitic capacitance **203**, and its potential variation amount ΔVf is $\{\Delta Vf=Q/Cf\}$ if an accumulated electric charge amount is Q and a parasitic capacitance value is Cf.

During a read operation, this displacement drives the vertical signal line **170** at a fixed gain via the amplifier circuit **118**.

As the third NMOS transistor as the separation transistor is omitted from the first embodiment, an area occupied by a pixel is reduced by the omission.

On the other hand, the FD **117**, which is the input node of the amplifier circuit **118** in a floating state, is easily affected by a state change of the second NMOS transistor **1122** adjacent thereto.

For example, when the first and second NMOS transistors **1121** and **1122** are turned on through the gate electrodes **201**, the potential of the FD **117** is changed by coupling thereof. As a result, there is the effect that some electrons to be accumulated in the channel portion of the second NMOS transistor **1122** are leaked to the FD **117**, which is the input node of the amplifier circuit **118**, or the like.

The FD **117**, which is the input node of the amplifier circuit **118**, includes a diffusion layer into which a large amount of impurities is introduced, a contact portion of a wiring, or the like, and has low crystallinity as compared to the channel portion of the MOS transistor.

Therefore, individually leaked electrons are easily lost by recombination or the like during the accumulation period, and particularly have significantly negative influence on the accumulation function of the third embodiment or the global shutter function of the ninth or tenth embodiment.

However, if electric charge accumulation capability is sufficiently large in the channel portion of the second NMOS transistor **1122**, it is possible in the thirteenth embodiment also to reduce or remove a margin limitation of a complete transfer in a principal similar to that of the first embodiment.

FIG. **28** is a diagram showing a cross-sectional structure example of the transfer circuit of FIG. **27**.

In the photodiode **111**, a HAD structure in which the vicinity of a silicon surface in contact with an oxide film has a p-type is adopted.

Here, the photoelectrically converted electrons are initially accumulated in the n-type diffusion node **204**.

If a signal that turns on the first NMOS transistor **1121** is applied to the gate electrode **201**, many electrons are transferred to the channel region of the second NMOS transistor **1122** via the first NMOS transistor **1121**, and accumulated in the channel region.

For example, an impurity profile of a channel portion is adjusted, so that a threshold of the first NMOS transistor **1121** is set to be high and a threshold of the second NMOS transistor **1122** is set to be low. Thereby, the channel portion of the second NMOS transistor **1122** forms an electron accumulation well, and the channel portion of the first NMOS transistor **1121** forms a potential wall of backflow prevention.

The diffusion layer **205** is connected to an input of the amplifier circuit **118**, which is not shown in the cross-sectional view.

Here, the first NMOS transistor **1121** and the second NMOS transistor **1122** are considered two individual transistors. However, they can be considered a single NMOS transistor having a gradient in the impurity profile of the channel portion if the gate electrodes are also integrally formed as shown in the figure.

In any case, it is functionally the same as two individual transistors connected in series, and is included in an application range of the present invention.

FIGS. **29**(A) to **29**(D) are diagrams showing potential changes accompanying a read transfer operation using the transfer circuit of the pixel circuit according to the thirteenth embodiment.

[Step T**41**]

In step ST**41** of FIG. **29**(A), the diffusion node **204** of the photodiode **111** is designed so that a potential bottom is about 2.5 V during full depletion in positive electric charge by a fixed number of donors. Here, it is filled with photoelectrically converted electrons up to a saturation state (about 0 V).

On the other hand, in the channel regions of the first NMOS transistor **1121** and the second NMOS transistor **1122**, potentials are respectively modulated in ranges of R**17** and R**18** according to a potential commonly applied to the two gate electrodes, for example, 1.5 V to 3 V.

The diffusion layer **205** (the FD **117**), which is the input node of the amplifier circuit **118**, is reset to have a floating state of 3 V.

[Step ST**42**]

If the first NMOS transistor **1121** and the second NMOS transistor **1122** are turned on in step ST**42** of FIG. **29**(B), a potential moves as follows.

Electrons accumulated in the diffusion node **204** of the photodiode **111** all move to the channel region of the second NMOS transistor **1122** via the first NMOS transistor **1121**.

In this case, the potential of the diffusion layer **205** (the FD **117**), which is the input node of the amplifier circuit **118**, rises by coupling. Some electrons further flow into the diffusion layer **205** (the FD **117**) via the channel portion of the second NMOS transistor **1122**.

That is, most electrons, which are a read signal, are accumulated in the channel region of the second NMOS transistor **1122** having a deep depletion state, and some electrons are accumulated in the diffusion layer **205** (the FD **117**), which is the input node of the amplifier circuit **118**.

[Step ST**43**]

The gate electrodes **201** are driven to turn off the first NMOS transistor **1121** and the second NMOS transistor **1122** in step ST**43** of FIG. **29**(C), so that the potential of the channel region is modulated in the negative direction.

Here, the channel of the first NMOS transistor **1121** forms a potential barrier, and prevents accumulated electrons from flowing back to the diffusion node **204** of the photodiode **111**. A height of the barrier corresponds to a difference between thresholds of the two transistors, for example, 1.5 V.

As the potential of the channel region of the second NMOS transistor **1122** rises (the potential decreases), electrons accumulated therein move to the diffusion layer **205** (the FD **117**), which is the input node of the amplifier circuit **118**.

[Step ST**44**]

In an OFF state of the first and second NMOS transistors **1121** and **1122** in step ST**44** of FIG. **29**(D), a state is reached in which all electrons accumulated in the photodiode in step S**41** have moved to the diffusion layer **205**, which is the input node of the amplifier circuit **118**. Thereby, the amplifier drives the vertical signal line, and an accumulated signal is read.

If the above-described step-by-step transfer is used, it is unnecessary to secure a potential difference between the diffusion node **204** of the photodiode **111** having the full depletion state and the diffusion layer **205**, which is the input node of the amplifier circuit **118**.

That is, in the thirteenth embodiment, a complete transfer is implemented even in a state in which the potential of the diffusion layer **205** (the FD **117**) filled with electrons is shallower than that of the diffusion node **204**.

To completely remove the above-described potential limitation during the transfer, the accumulation capacity of the channel portion of the second NMOS transistor **1122** is sufficiently increased in step ST**42**. Thereby, it is necessary to move all electrons to the right side from the second NMOS transistor **1122**, regardless of the magnitude of the parasitic capacitance of the diffusion layer **205**, which is the input node of the amplifier circuit **118**.

If the saturated accumulated electric charge amount of the photodiode is Qs, a channel capacity of the second NMOS transistor **1122** (a capacity of an inversion layer) is Cinv, and a threshold difference between the first NMOS transistor **1121** and the second NMOS transistor **1122** is ΔVth, the following condition is given.

$$|Cinv*\Delta Vth|>|Qs| \quad \text{[Expression 3]}$$

Actually, there is an advantageous effect in that a transfer margin sufficiently significantly extends if a state is reached in which half or more of electrons generated by photoelectric conversion of the photodiode **111** have been accumulated in the channel portion of the second NMOS transistor **1122** in step ST**42**.

14. Fourteenth Embodiment

FIG. **30** is a diagram showing a pixel circuit of a CMOS imager according to a fourteenth embodiment of the present invention.

A difference between a pixel circuit **110**F according to the fourteenth embodiment and the pixel circuit **110**E according to the thirteenth embodiment is as follows.

In the pixel circuit **110**F according to the fourteenth embodiment, a plurality of pixels, for example, two pixels PXL**110***a* and PXL**110***b*, respectively having a unique photodiode **111** and a unique transfer circuit **112**, share FD **117** and an amplifier transistor **114** forming an amplifier circuit.

In the pixel circuit **110**F, the plurality of pixels PXL**110***a* and PXL**110***b* also share a reset transistor **113** and a row selection transistor **115**.

In transfer transistors **112***a* and **112***b* of the respective pixels PXL**110***a* and PXL**110***b*, shared gate electrodes of first and second NMOS transistors are respectively connected to different transfer lines **140***a* and **140***b*.

In the pixel circuit **110**F, electrons accumulated in respective photodiodes **111***a* and **111***b* are transferred to the FD **117** (the input node of the amplifier circuit) at individual timings according to the respectively independent transfer lines **140***a* and **140***b*.

The sharing of the amplifier circuit can reduce an effective size of the pixel, but parasitic capacitance of the FD **117** also increases when the number of sharing pixels increases.

Therefore, it is preferable that the number of sharing pixels be equal to or greater than 2 and equal to or less than 16.

The embodiments using the photodiode in a photoelectric conversion element of a semiconductor imager have been described above.

On the other hand, a MOS capacitor may be used in the photoelectric conversion element. It is possible to obtain the same effect even when the MOS capacitor is used in place of the photodiode in the first to fourteenth embodiments.

15. Fifteenth Embodiment

FIG. **31** is a diagram showing a configuration example of a transfer circuit according to a fifteenth embodiment in which the photodiode is replaced with a MOS capacitor with respect to FIG. **6**, which is a cross-sectional structure example corresponding to the first embodiment.

In FIG. **31**, reference numeral **210** denotes a photoelectric conversion element using a MOS capacitor.

For example, a fixed voltage of 2 V is applied to an electrode **211**, and a MOS capacitor **210** has a deep depletion state.

If electrons enter the depletion layer, electron/hole pairs are generated. Holes are attracted to an electric field and go to a p-well side. On the other hand, the electrons are accumulated in the vicinity of an oxide film of the MOS capacitor **210** as an inversion layer.

If the gate electrode **201** has the high level, the accumulated electrons are completely transferred to the channel region of the second NMOS transistor **1122** via the first MOS transistor **1121**, and accumulated in the channel region.

Further, if the level of the gate electrode **201** falls to the low level, the accumulated electrons are transferred to the diffusion layer **205** (the FD **117**), which is the input node of the amplifier circuit, the vertical signal line **170** is driven, and the read is performed.

16. Sixteenth Embodiment

FIG. **32** is a diagram showing a cross-sectional structure example of a transfer circuit according to a sixteenth embodiment having a cross-sectional structure different from the transfer circuit of the first embodiment.

A main difference between the transfer circuit according to the sixteenth embodiment of FIG. **32** and the transfer circuit according to the first embodiment of FIG. **6** is an integrated gate structure of the integrated first to third NMOS transistors **1121**, **1122**, and **1123**.

In the sixteenth embodiment, the first NMOS transistor **1121** and the second NMOS transistor **1122** are formed using different gate electrodes **201-1** and **201-2**.

The gate electrodes **201-1** and **201-2** are formed of different conductive layers or polysilicon layers, and short-circuited within a pixel (not shown) to form an integrated electrode **201**.

In this structure, it is possible to adjust a substrate impurity profile of the second NMOS transistor **1122** in self alignment. Alternatively, it is also possible to adjust a threshold by changing work functions of different gate electrode layers.

The solid-state image pickup device according to the first to sixteenth embodiments described above may be applied as an image pickup device of a digital camera or a video camera.

17. Seventeenth Embodiment

FIG. **33** is a diagram showing an example of a configuration of a camera system to which a solid-state image pickup device is applied according to an embodiment of the present invention.

As shown in FIG. **33**, a camera system **300** has an image pickup device **310** to which the CMOS image sensors (solid-state image pickup devices) **100** is applicable.

The camera system **300** has an optical system, which guides incident light to a pixel region of the image pickup device **310** (or which forms an image of a subject), for example, a lens **320**, which forms an image of the incident light (an optical image) on an image pickup surface.

Further, the camera system **300** has a driving circuit (DRV) **330**, which drives the image pickup device **310**, and a signal processing circuit (PRC) **340**, which processes an output signal of the image pickup device **310**.

The driving circuit **330** has a timing generator (not shown), which generates various timing signals including a start pulse or a clock pulse to drive a circuit within the image pickup device **310**, and drives the image pickup device **310** by a predetermined timing signal.

The signal processing circuit **340** performs predetermined signal processing for the output signal of the image pickup device **310**.

An image signal processed by the signal processing circuit **340** is recorded, for example, on a recording medium such as a memory. Image information recorded on the recording medium is hard-copied by a printer or the like. The image signal processed by the signal processing circuit **340** is displayed on a monitor including a liquid crystal display or the like as a moving image.

In an image pickup apparatus of a digital still camera or the like as described above, a high-precision camera can be implemented at low power consumption by mounting the above-described image pickup device **100** as the image pickup device **310**.

REFERENCE SIGNS LIST

100: CMOS image sensor
110: Pixel array section
110A to **110**F: Pixel circuit
111: Photodiode
112: Transfer transistor
1121: First MOS transistor

130: Column read circuit (AFE)
300: Camera system

What is claimed is:

1. A solid state imaging device comprising:
an amplifier transistor, an input node for the amplifier transistor, or both the amplifier transistor and the input node for the amplifier transistor;
a plurality of photoelectric conversion elements;
a same plurality of storage transistors, each configured to act as a photo-charge storage node to store charges generated by a respective photoelectric conversion element; and
a same plurality of transfer transistors, each configured to transfer charges from a respective photoelectric conversion element to a common output, the common output being either the amplifier transistor or the input node for the amplifier transistor.

2. The solid state imaging device of claim **1**, wherein each storage transistor is electrically between its respective photoelectric conversion element and its respective transfer transistor.

3. The solid state imaging device of claim **2**, wherein each photoelectric conversion element is a pinned photodiode.

4. The solid state imaging device of claim **1**, wherein a gate electrode of each transfer transistor has a fixed potential.

5. The solid state imaging device of claim **1**, wherein:
each storage transistor is comprised of a first and a second transistor, and
the first and second transistors have gate electrodes that are simultaneously collectively driven, and a threshold voltage of the first transistor is set to be higher than that of the second transistor.

6. The solid-state imaging device of claim **1**, wherein the input node for the amplifier transistor is a floating diffusion region.

7. The solid-state imaging device of claim **1**, wherein:
the solid-state imaging device comprises both the amplifier transistor and the input node for the amplifier transistor,
each storage transistor is electrically between its respective photoelectric conversion element and its respective transfer transistor,
the input node for the amplifier transistor is a floating diffusion region,

each transfer transistor is connected to transfer charges from its respective storage transistor to the floating diffusion region, and

a gate of the amplifier transistor is connected to the floating diffusion region.

8. An electronic device comprising:

a solid-state imaging circuitry, the solid-state imaging device comprising (a) an amplifier transistor, an input node for the amplifier transistor, or both the amplifier transistor and the input node for the amplifier transistor, (b) a plurality of photoelectric conversion elements, (c) a same plurality of storage transistors, each configured to act as a photo-charge storage node to store charges generated by a respective photoelectric conversion element, and (d) a same plurality of transfer transistors, each configured to transfer charges from a respective photoelectric conversion element to a common output, the common output being either the amplifier transistor or the input node for the amplifier transistor; and

processing circuitry to process signals generated by the solid-state image circuitry.

9. The electronic device of claim **8**, wherein each storage transistor is electrically between its respective photoelectric conversion element and its respective transfer transistor.

10. The electronic device of claim **9**, wherein each photoelectric conversion element is a pinned photodiode.

11. The electronic device of claim **8**, wherein a gate electrode of each transfer transistor has a fixed potential.

12. The electronic device of claim **8**, wherein:

each storage transistor is comprised of a first and a second transistor, and

the first and second transistors have gate electrodes that are simultaneously collectively driven, and a threshold voltage of the first transistor is set to be higher than that of the second transistor.

13. The electronic device of claim **8**, wherein the input node for the amplifier transistor is a floating diffusion region.

14. The electronic device of claim **8**, wherein:

the solid-state imaging circuitry comprises both the amplifier transistor and the input node for the amplifier transistor,

each storage transistor is electrically between its respective photoelectric conversion element and its respective transfer transistor,

the input node for the amplifier transistor is a floating diffusion region,

each transfer transistor is connected to transfer charges from its respective storage transistor to the floating diffusion region, and

a gate of the amplifier transistor is connected to the floating diffusion region.

15. A solid-state imaging device comprising:

a floating diffusion region;

a reset transistor operatively coupled to the floating diffusion region to effect a reset thereof;

a plurality of photoelectric conversion elements;

a same plurality of storage transistors, each configured to act as a photo-charge storage node to store charges generated by a respective photoelectric conversion element; and

a same plurality of transfer transistors, each configured to transfer charges from a respective photoelectric conversion element to floating diffusion region.

16. The solid state imaging device of claim **15**, wherein each photoelectric conversion element is a pinned photodiode.

17. A solid-state imaging device comprising:

a floating diffusion region;

a reset transistor operatively coupled to the floating diffusion region to effect a reset thereof;

an amplifier transistor with a gate coupled to the floating diffusion region;

a plurality of photoelectric conversion elements;

a same plurality of storage transistors, each configured to act as a photo-charge storage node to store charges generated by a respective photoelectric conversion element; and

a same plurality of transfer transistors, each configured to transfer charges from a respective photoelectric conversion element to the floating diffusion region.

18. The solid state imaging device of claim **17**, wherein each photoelectric conversion element is a pinned photodiode.

19. A solid-state imaging device comprising:

a floating diffusion region;

a reset transistor operatively coupled to the floating diffusion region to effect a reset thereof;

an amplifier transistor with a gate coupled to the floating diffusion region;

a plurality of photoelectric conversion elements;

a same plurality of storage transistors, each operatively connected and configured to receive charges generated by is respective photoelectric conversion element and to act as a photo-charge storage node to store the charges generated by a respective photoelectric conversion element; and

a same plurality of transfer transistors, each operatively connected and configured to transfer charges from a respective storage transistor to the floating diffusion region.

20. The solid state imaging device of claim **19**, wherein each photoelectric conversion element is a pinned photodiode.
