(57) **ABSTRACT**  
Treatment methods and devices are provided for percutaneously accessing a patient's thoracic region via a controlled opening in the aorta, so that cardiac procedures, such as a coronary bypass procedure, can be performed in a minimally invasive manner. Advantageously, it may be possible to perform the procedure without placing the patient on cardiopulmonary bypass. The method may include percutaneously delivering at least one catheter into an aorta of a heart, forming a controlled opening in the aorta and pericardium via the at least one catheter to access a thoracic region within the patient's chest, and performing at least one coronary bypass graft procedure through the controlled opening.

## MINIMALLY INVASIVE METHOD FOR CORONARY BYPASS AND OTHER TREATMENTS

### CROSS-REFERENCE TO RELATED APPLICATIONS

This application is a divisional of U.S. patent application Ser. No. 12/329,052, filed Dec. 5, 2008, which claims the benefit of U.S. Provisional Application No. 60/992,860, filed Dec. 6, 2007. These applications are incorporated herein by reference in their entirety.

### BACKGROUND OF THE INVENTION

The present invention relates generally to minimally invasive methods for performing cardiac medical and/or surgical procedures, and more particularly to percutaneous methods for performing a coronary artery bypass graft (CABG) procedure on a patient in need thereof

Coronary artery disease remains a leading cause of morbidity and mortality in Western societies. A number of approaches have been developed for treating coronary artery disease. It is often sufficient to treat the symptoms with pharmaceuticals and lifestyle modification to lessen the underlying causes of the disease. In more severe cases, the coronary stenoses may be treated endovascularly using techniques such as balloon angioplasty, atherectomy, laser ablation, stenting, thrombectomy, and the like.

In still more severe cases where pharmaceutical treatment and/or conventional endovascular approaches have failed or are likely to fail, it may be necessary to perform a coronary artery bypass graft procedure using open surgical techniques. Such techniques require that a patient's sternum be opened, the chest spread apart to provide access to the heart, and the heart stopped. While very effective in many cases, the use of open surgery to perform coronary artery bypass grafting is highly traumatic to the patient. The procedure requires immediate postoperative care in an intensive care unit, hospitalization for five to ten days, and a recovery period as long as six to eight weeks.

Alternative techniques have been devised to perform coronary bypass surgical procedures thoroscopically. Examples of such procedures are disclosed in U.S. Pat. No. 7,131,447 and No. 7,028,692 to Sterman et al., and in U.S. Pat. No. 5,888,247 to Benetii. Although such methods are believed to decrease morbidity, mortality, cost, and recovery time when compared to conventional open surgical coronary bypass procedures, they still require stopping the patient's heart and placing the patient on cardiopulmonary bypass.

It would be desirable to provide a better method for performing a coronary bypass procedure that is less invasive than open surgical or thoroscopic techniques. It would also be desirable to provide an interventional procedure that does not require use of cardiopulmonary bypass.

### SUMMARY OF THE INVENTION

Methods and devices are provided for performing a medical procedure on a patient's heart. In one aspect, the method includes (i) percutaneously delivering at least one catheter into an aorta of the heart; (ii) forming a hemostatic connection between the at least one catheter and an inner wall of the aorta; (iii) creating an aperture through the aorta and pericardium, said aperture being bounded by the hemostatic connection, thereby forming a controlled opening to access a thoracic region of the patient's chest through the at least one catheter;

2

and (iv) performing a cardiac procedure through the controlled opening. In one embodiment, a method is provided for performing a coronary bypass procedure on a patient's heart comprising: (i) percutaneously inserting an end of at least one catheter into the ascending aorta; (ii) forming a controlled opening in a wall of the aorta via a lumen of the inserted end of the at least one catheter, wherein the controlled opening is outwardly directed from the wall of the aorta into a thoracic region within the patient's chest; and (iii) performing at least one coronary bypass graft procedure through the controlled opening.

### BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 illustrates a catheter disposed in a partial sectional view of a human heart and its associated proximate vascular system.

FIG. 2 illustrates a view of the heart of FIG. 1 with a hemostatic connection between the catheter and aorta according to one embodiment.

FIG. 3A illustrates a catheter according to one embodiment.

FIG. 3B illustrates a hemostatic connection and controlled opening in the aortic wall of the heart shown in FIG. 2.

FIGS. 4A and 4B illustrate a flange in a non-expanded and expanded position in and extending from a catheter according to one embodiment.

FIG. 5 illustrates a device and method for forming a hemostatic connection between the catheter and aorta according to one embodiment.

FIG. 6 illustrates a device and method for forming a hemostatic connection between the catheter and aorta according to another embodiment.

FIG. 7 illustrates a view of the heart of FIG. 1 undergoing a coronary bypass graft procedure according to one embodiment.

FIG. 8 illustrates a view of the heart of FIG. 5 undergoing a coronary bypass graft procedure according to one embodiment.

FIGS. 9A and 9B illustrate a lock and key stent for use in a coronary bypass graft procedure before and after, respectively according to one embodiment.

FIGS. 10A and 10B illustrate a magnetically linked catheter both before and after passage of a loop glide wire from a first catheter to a second catheter.

FIG. 11 illustrates a stent for the formation of an end-to-side anastomosis in a coronary bypass graft procedure according to one embodiment.

### DESCRIPTION OF THE INVENTION

Methods and devices are provided for performing a variety of cardiac medical procedures on a patient in a minimally invasive manner. As used herein, the term "patient" refers primarily to a human adult or child, but also may include other suitable mammalian animals, for example in a pre-clinical trial or in veterinary care.

The interventional medical procedure preferably is conducted percutaneously, which involves accessing the heart via a blood vessel and a catheter introduced therein using a needle puncture. A wire may be introduced through the lumen of a needle and catheters can be delivered over the wire into the blood vessel and guided to the heart. In a preferred embodiment, the procedures may be conducted without placing the patient on cardiopulmonary bypass.

In one aspect, a method is provided for percutaneously performing a cardiac procedure on a patient's heart. In one

embodiment, the method includes the steps of percutaneously delivering at least one catheter into the aorta above the beating heart; forming a hemostatic connection between the at least one catheter and an inner wall of the aorta or other vascular structure; creating an aperture through the ascending thoracic aorta or other vascular structure acting as an inflow conduit, said aperture being bounded by the hemostatic connection, thereby forming a controlled opening to access a thoracic region of the patient's chest through the at least one catheter; and performing a cardiac procedure through the controlled opening. In one embodiment, the cardiac procedure is a coronary bypass graft procedure. In other embodiments, the cardiac procedure may be a valve repair, a valve replacement, or a thermal and mechanical cardiac ablation procedure to correct arrhythmias. Other procedures known in the art may also be adapted to be performed through the controlled opening.

In a preferred embodiment, the procedure is conducted using computed tomography (CT) guidance. In another preferred embodiment, the at least one catheter comprises a Hansen Device™. These guidance tools are known in the art for use with conventional cardiac interventions.

In one embodiment, the coronary bypass graft procedure includes the steps of detaching a left internal mammary artery from a patient's inner thoracic wall; occluding blood flow in the left internal mammary artery; transecting a distal end of the left internal mammary artery; forming an anastomosis between the distal end of the left internal mammary artery and a coronary artery targeted for bypass; closing the controlled opening in the aorta and pericardium; and withdrawing the at least one catheter from the aorta.

The percutaneous coronary bypass graft procedure may be conducted as follows. The patient undergoing the procedure may be prepared in a conventional manner for cardiac catheterization with both groins prepared to permit access to the femoral arteries and veins and with the arms prepared to permit access to the radial or brachial arteries and veins. The patient may be sedated for the procedure using any appropriate means, including general anesthesia. Once anesthetized, the patient may be intubated with a double-lumen endobronchial tube, for example, which allows for the selective ventilation or deflation of the right and left lungs. The procedure generally should be conducted under systemic anticoagulation, such as with either heparin or bivalirudin, and in the presence of an effective antiplatelet therapy, such as aspirin and/or a thienopyridine drug, like Clopidogrel, or other antiplatelet agents.

After the patient has been prepared for the procedure, appropriate incisions are made and a catheter **110** is guided toward the heart **10** from the descending aorta **12** through the aortic arch **14** into the ascending aorta **16** (FIG. **1**). The procedure generally may be conducted using fluoroscopic guidance or CT guidance to obtain the desired visualization. Other visualization techniques well known in the art, such as MRI, ultrasound, stereotaxis, also may be used.

Access from the left and right femoral arteries may be achieved in the usual fashion and a guide may be advanced to the ostium of the left coronary or the right coronary as is typically performed with angioplasty. Through this guide, a guidewire may be advanced across an anatomic stenosis in the right or left coronary system using conventional techniques. Another catheter **110** then may be advanced using the contralateral femoral access.

In one embodiment, the catheter **110** is used to form a hemostatic connection **112** with the inner aortic wall **18** in an anterolateral, or otherwise preferred, projection. Alternatively, the hemostatic connection may be made with the inner wall of any other suitable large vascular structure. The term

“hemostatic connection” as used herein means a connection that substantially prevents the flow of blood or other fluids at the interface of the device and inner vascular wall (i.e., the lumen-aortic interface or catheter-aortic interface) (FIG. **2**).

In one embodiment, the catheter **110** includes a flange **114** that is part of the catheter itself (FIG. **3A**). The flange **114** may expand upon removal of a sleeve **115** that keeps the flange in a non-expanded form until the distal end of the catheter **110** is in the desired position within the aorta, for example (FIGS. **4A** and **4B**). Those skilled in the art will appreciate that the flange may assume any suitable shape, non-limiting examples of which include a rectangular, circular, or elliptical form.

The hemostatic connection between the catheter and the inner aortic wall may be made using any suitable technique, including suction adherence, removable suture adherence, or magnetic pull from a source outside the body on the chest wall. For example, in one embodiment, the hemostatic connection **112** may be created by forming sutures **116** through the catheter wall **110** to the inner aortic wall **18**, which may be tightened during the procedure as needed and removed after the procedure has been completed. The hemostatic connection **112** also may be created by inflating a non-occluding balloon **117** within the aorta **16** (FIG. **5**). The non-occluding balloon should be inflated in such a way that it provides a sufficient amount of pressure against the flange **114**, thereby forming a hemostatic connection between the flange and the inner aortic wall **18**. Such non-occluding balloons are known to those in the art, non-limiting examples of which are disclosed in U.S. Patent Publication No. 2007/0021818 to De Gregorio and U.S. Patent Publication No. 2004/0102732 to Naghani et al. In one embodiment, the hemostatic connection **112** may be created by extending one or more counter-supports **119** within the aorta **16** opposite the flange **114** (FIG. **6**). The one or more counter-supports should provide a sufficient amount of pressure to secure the flange **114** against the inner aortic wall **18** and form a hemostatic connection **112**.

After the hemostatic connection **112** between the catheter **110** and inner aortic wall **18** has been established, a controlled wall opening **118** is created through the aortic wall into the thorax (not shown) using any suitable technique or device for forming the penetration. Non-limiting examples of such techniques may include use of a trocar through the catheter or use of a laser to create the controlled opening. In one embodiment, the aorto-thoracic controlled opening may be maintained by an anchoring device delivered through the catheter, such as a self-expanding or balloon expandable fixator. This anchoring device may remain or be removed upon aorto-coronary conduit placement. The controlled opening provides an access point for a joystick-driven blunt-tipped catheter, which may be manipulated under CT or MR guidance. Desirably, the catheter may be manipulated 360 degrees. Non-limiting examples of such catheters include the CT-guided Hansen Device™ (Hansen Medical, Mountain View, Calif.) or the MR-guided Stereotaxis Magnetic Navigation System™ (Stereotaxis Inc., St. Louis, Mo.).

With the left lung selectively deflated, the joystick driven catheter then may be used to dissect within the thorax to the pericardium. Once the pericardium may be visualized directly, access to the pericardium may be achieved using a mechanical puncture or laser opening. A guidewire may then be passed into the pericardium, thereby allowing a balloon occluding device to be advanced over the guidewire such that either side of the balloon would allow the center of the balloon (e.g., a dogbone shape) to forcibly tamponade the hole in the pericardium. After removing the wire, the pericardium then may be insufflated with carbon dioxide via the balloon to provide space in which to work in the pericardium. Alterna-

tively, the pericardium may be simply incised and opened for direct access to the cardiac anatomy.

Once access to the thorax has been accomplished with the left lung selectively deflated, the left internal mammary artery **20** may be taken down from the patient's inner thoracic wall percutaneously by a Hansen Device™ or other suitable device **120** which is advanced through the catheter **110** (FIG. 7). Those skilled in the art will appreciate that access and manipulation of the left internal mammary artery may be achieved from a variety of different positions, non-limiting examples of such positions include the radial, brachial, or axillary positions, depending upon the selected access sheath and device size. In one embodiment, the left internal mammary artery is accessed by first selectively deflating the left lung through the endotracheal tube and maintaining ventilatory support through the right lung. The blood flow in the internal mammary artery **20** typically is stopped before take-down of the artery by introducing a separate catheter **122** through the left radial artery and subclavian artery **22** into the internal mammary artery and inflating a balloon **124** at the distal tip of the artery to occlude blood flow. In another embodiment, the blood flow in the left internal mammary artery is stopped using a proximal flow-occluding device. After occlusion of the blood flow within the left internal mammary artery **20**, a laser tipped catheter **120** may be advanced through the aorto-thoracic catheter **110** via the controlled opening **118**, and used to cut and seal the side branches of the left internal mammary artery **20**, to dissect the left internal mammary artery from the thoracic wall, and to transect the distal tip of the artery. This process may involve simultaneous manipulation of the left radial-to-left internal mammary artery catheter **122**, and the aorto-thoracic catheter **110** together to avoid trauma to the left internal mammary artery **20** as it is being taken down from the inner thoracic wall. Suitable laser tipped catheters are known in the art, or may be fashioned to achieve this end (e.g., holmium lasers). Other commonly used interventional cardiology or surgical devices may also be employed to this end.

After harvesting and preparing the left internal mammary artery **20** for anastomosis, the target site of the coronary artery to be bypassed is identified. Typically, the diseased coronary artery which is the subject of the bypass is the left anterior descending (LAD) artery **24** (FIG. 8); however, the methods provided herein also are suitable for bypassing other arteries, including the right coronary artery, the obtuse marginal artery, the ramus intermedius artery, and the posterior descending artery.

After the take-down and transection of the left internal mammary artery **20**, the left internal mammary artery may be manipulated and repositioned toward the opening of the pericardium (not shown) toward the surface of the LAD **24** on the top of the heart (not shown). In one embodiment, a pair of magnetic tipped catheters is used to align the left internal mammary artery and LAD. A non-limiting example of such a catheter is the MagneCath™ (Ample Medical, Foster City, Calif.). In one embodiment, a first MagneCath™ **126** is disposed in the LAD **24** (the endovascular MagneCath™) and a second MagneCath™ **122** is disposed in the left internal mammary artery **20** (the epivascular MagneCath™). The first and second MagneCath™ then are used to align the left internal mammary artery and LAD (FIGS. 9A and 9B).

The MagneCath™ provides two complimentary shaped permanent magnets **132,134** on the distal tip of the catheter **122,126** which link together (FIGS. 10A and 10B, illustrated in Circulation 113:2329-2334, 2330 (2006)). Such a device allows an exact linkage between the first MagneCath™ in the LAD distal to the significant coronary lesion and the second

MagneCath™ in the left internal mammary artery at the epicardial coronary distal to the lesion. The MagneCath™ **126** is a hypotube with a guidewire lumen **136** and magnet **134** at the distal tip that complementarily attaches to the interlocking magnet **132** of a second MagneCath™ **122**. The attachment of the two MagneCath™ allows for the forceable puncturing from one hypotube through the MagneCath™ **126** into the second MagneCath™ **122**. Once passed through the complimentary MagneCath™, the guidewire **136** acts as a tether over which one can deliver devices, balloons, or in this case attach one vascular structure to another.

The MagneCath™ tips on either side of the selected artery wall of interest (for example, the left internal mammary artery or LAD) may be manipulated such that they link magnetically. After the catheters are mated, a crossing guidewire **136** may be advanced from the endovascular MagneCath™ **126** into the epivascular MagneCath™ **122**, linking the two devices. This guidewire **136** may then be passed from the artery into the aorto-thoracic catheter **110** and externalized as a continuous right common femoral artery-to-left common femoral artery loop or right common femoral artery-to-left radial artery loop to remove the MagneCath™. Over this guidewire, a proximal occlusion balloon may be used to interrupt blood flow within the selected coronary artery, while manipulation in the epicardial space is performed.

In one embodiment, a locking vascular connector is implanted on the distal tip of the left internal mammary artery **20** via a thoracotomy in the anterior chest wall after the take-down of the left internal mammary artery **20** and before the movement of the left internal mammary artery into position (FIGS. 9A and 9B). Alternatively, a stent **130** may be placed in the LAD **24** to allow for use of an occlusion balloon catheter in the LAD, thereby accommodating use of an end-to-side anastomosis between the left internal mammary artery and LAD (FIG. 11).

In one embodiment, the tip of the left internal mammary artery is affixed to the LAD with a stent-like self-expanding nitinol vascular connector, which allows for anastomosis to the coronary. The vascular connector may comprise a singular device or multiple separate but complimentary or cooperative devices **127, 128** (e.g., a lock and key) disposed in the left internal mammary artery **20** and in the LAD **24** (FIGS. 9A and 9B). The vascular connector **127** may be applied to the tip of the left internal mammary artery **20** using direct force applied from the lumen outwardly or by suture to the left internal mammary artery through the patient's chest using a thoracotomy or through the aortothoracic catheter or the radial catheter, while the vascular connector **128** may be attached to the LAD using direct expansive force. In a particular embodiment, the vascular connector **128** may be deployed by removal of a sheath closure mechanism, similar to currently known or commercially available self-expanding stents. The vascular connector may further comprise a drug coating, similar to currently available drug eluting stents.

Other techniques known to those skilled in the art for joining the internal mammary artery and the LAD include suturing, laser welding, microstapling, using a bioadhesive (e.g., BioGlue™) or a combination thereof.

Following completion of the coronary anastomosis, the balloon occluding catheter of the left internal mammary artery may be deflated and removed, allowing blood to flow through the left internal mammary artery into the LAD. The catheter and Hansen Device™ is withdrawn from the thorax back through the catheter lumen-aortic interface, the aortic wall closed (sealed), and the catheters withdrawn. The groin and radial penetrations finally may be repaired as necessary.

It also is contemplated herein that a similar approach may be taken with the right internal mammary artery or using harvested saphenous veins. For example, in an alternative embodiment, a saphenous vein may be harvested from any suitable location. In one alternative embodiment, an arterial graft is harvested from the gastroepiploic artery, the gastric artery, the radial artery, the femoral artery, the splenic artery, or the like. Two vascular connectors may be applied to each end of the vein or arterial conduit to allow the vein or artery to be pulled forcibly or advanced using the MagneCath™-delivered guidewire. A flexible-tipped guidewire may be passed through the coronary catheter down the vessel, out the coronary artery through the MagneCath™ into the lumen of the pericardial balloon, and then out the catheter through the aorta to the femoral artery. The vein then may be advanced over the guidewire through the aortothoracic catheter into the thorax, down the wire through the pericardium, and attached to the coronary artery. A coronary arteriotomy may be necessary to advance a vein with a vascular connector over the tip. Once anastomosed to the coronary at the distal tip of the vein, the proximal aspect of the vein may be anastomosed to the thoracic aorta. A self-expanding nitinol vascular connector at either end of the vein optionally may be expanded. Such a procedure would provide an alternative method for coronary revascularization, providing a conduit for flow from the thoracic aorta down to the coronary artery.

Thus, the procedures described herein provide an approach for utilizing percutaneous and aorto-thoracic means of facilitating anastomosis of bypass conduits, the left or right internal mammary artery, or saphenous vein bypass grafts, achieving procedures which otherwise would require open chest coronary artery bypass grafting around significant stenoses in the native coronary anatomy. It is believed that such procedures may result in decreased morbidity, mortality, cost, and recovery time when compared to conventional surgical coronary bypass procedures.

Publications cited herein and the materials for which they are cited are specifically incorporated herein by reference. Modifications and variations of the methods and devices described herein will be obvious to those skilled in the art from the foregoing detailed description. Such modifications and variations are intended to come within the scope of the appended claims.

I claim:

1. A device for performing a medical procedure on a patient's heart comprising:  
 a catheter for percutaneous delivery of a hemostatic connector into an aorta of a heart;  
 a flange configured to releasably form a hemostatic connection between the catheter and an inner wall of the aorta to form a catheter-aortic interface, wherein the hemostatic connection substantially prevents blood from flowing through the catheter-aortic interface;  
 a non-occluding balloon member for releasably securing, upon inflation, the flange to the inner wall, wherein inflation of the non-occluding balloon member does not substantially interfere with blood flow through the aorta; and  
 a penetration device for forming an aperture through the aorta into a pericardium, wherein the aperture is bounded by the hemostatic connection, thereby forming a controlled opening to access a thoracic region of the patient's chest through the catheter,  
 wherein the device is adapted to form the hemostatic connection before forming the controlled opening to access the thoracic region.

2. The device of claim 1, further comprising an anchoring device for maintaining the controlled opening.

3. The device of claim 2, wherein the anchoring device comprises a self-expanding or balloon-expandable fixator.

4. The device of claim 1, further comprising a sleeve disposed around at least a portion of the flange and configured to temporarily maintain the flange in a non-expanded form.

5. A device for performing a medical procedure on a patient's heart comprising:

a catheter for percutaneous delivery of a hemostatic connector into an aorta of a heart;

a flange configured to releasably form a hemostatic connection between the catheter and an inner wall of the aorta to form a catheter-aortic interface, wherein the hemostatic connection substantially prevents blood from flowing through the catheter-aortic interface;

one or more counter-supports to the flange for releasably securing the flange against the inner wall, wherein the one or more counter-supports protrude radially from the catheter opposite the catheter-aortic interface; and

a penetration device for forming an aperture through the aorta into a pericardium, wherein the aperture is bounded by the hemostatic connection, thereby forming a controlled opening to access a thoracic region of the patient's chest through the catheter,

wherein the device is adapted to form the hemostatic connection before forming the controlled opening to access the thoracic region.

6. The device of claim 5, further comprising an anchoring device for maintaining the controlled opening.

7. The device of claim 6, wherein the anchoring device comprises a self-expanding or balloon-expandable fixator.

8. The device of claim 5, further comprising a non-occluding balloon member which upon inflation does not substantially interfere with blood flow through the vessel.

9. A device for percutaneous revascularization comprising:

a catheter for percutaneous delivery into a vessel of a patient, the catheter having a proximal end, a distal end, and at least one lumen extending from the proximal end to the distal end;

a flange extending from the distal end of the catheter, the flange configured to releasably form a hemostatic connection between the catheter and an inner wall of the vessel without substantially interfering with blood flow through the vessel; and

one or more counter-supports to the flange protruding radially from the catheter, the one or more counter-supports configured to releasably secure the flange to the inner wall of the vessel,

wherein the hemostatic connection substantially prevents blood flow at an interface of the distal end of the catheter and the inner wall of the vessel, and

wherein the at least one lumen of the catheter is configured to provide access to the vessel wall while maintaining the hemostatic connection.

10. The device of claim 9, further comprising a means for forming an aperture through the vessel wall, the aperture being bounded by the hemostatic connection, providing a controlled opening to access outside the vessel via the at least one lumen of the catheter.

11. The device of claim 10, further comprising an anchoring device for maintaining the controlled opening.

12. The device of claim 11, wherein the anchoring device comprises a self-expanding or balloon-expandable fixator.

13. The device of claim 9, further comprising a sleeve disposed around at least a portion of the flange and configured to temporarily maintain the flange in a non-expanded form.

**9**

**10**

**14.** The device of claim **9**, further comprising a non-occluding balloon member which upon inflation does not substantially interfere with blood flow through the vessel.
