(57) **ABSTRACT**
Described herein are embodiments of stationary exercise machines having reciprocating foot and/or hand members, such as foot pedals that move in a closed loop path. Some embodiments can include reciprocating foot pedals that cause a user's feet to move along a closed loop path that is substantially inclined, such that the foot motion simulates a climbing motion more than a flat walking or running motion. Some embodiments can further include reciprocating handles that are configured to move in coordination with the foot via a linkage to a crank wheel also coupled to the foot pedals. Variable resistance can be provided via a rotating air-resistance based mechanism, via a magnetism based mechanism, and/or via other mechanisms, one or more of which can be rapidly adjustable while the user is using the machine.

EXERCISE MACHINECROSS-REFERENCE TO RELATED
APPLICATIONS

This application is a continuation-in-part of U.S. patent application Ser. No. 14/218,808, filed Mar. 18, 2014, and entitled "Exercise Machine," which is a continuation of PCT International Patent Application No. PCT/US2014/030875, filed on Mar. 17, 2014, entitled "Exercise Machine," which claims, under 35 U.S.C. § 119(e), the benefit of U.S. Provisional Patent Application No. 61/798,663, filed on Mar. 15, 2013, entitled "Exercise Machine." All of these applications are hereby incorporated by reference in their entirety.

TECHNICAL FIELD

This application concerns stationary exercise machines having reciprocating members.

BACKGROUND

Traditional stationary exercise machines include stair climber-type machines and elliptical running-type machines. Each of these types of machines typically offers a different type of workout, with stair climber-type machines providing for a lower frequency vertical climbing simulation, and with elliptical machines providing for a higher frequency horizontal running simulation. Additionally, if these machines have handles that provide upper body exercise, the connection between the handles, the foot pedals/pads, and/or the flywheel mechanism provide an insufficient exercise experience for the upper body.

It is therefore desirable to provide an improved stationary exercise machine and, more specifically, an improved exercise machine that may address or improve upon the above-described stationary exercise machines and/or which more generally offers improvements or an alternative to existing arrangements.

SUMMARY

Described herein are embodiments of stationary exercise machines having reciprocating foot and/or hand members, such as foot pedals that move in a closed loop path. Some embodiments can include reciprocating foot pedals that cause a user's feet to move along a closed-loop path that is substantially inclined, such that the foot motion simulates a climbing motion more than a flat walking or running motion. Some embodiments can further include reciprocating handles that are configured to move in coordination with the foot via a linkage to a crank wheel also coupled to the foot pedals. Variable resistance can be provided via a rotating air-resistance based mechanism, via a magnetism based mechanism, and/or via other mechanisms, one or more of which can be rapidly adjustable while the user is using the machine.

Some embodiments of a stationary exercise machine comprise first and second reciprocating foot pedals each configured to move in a respective closed loop path, with each of the closed loop paths defining a major axis extending between two points in the closed loop path that are furthest apart from each other, and wherein the major axis of the closed loop paths is inclined more than 45° relative to a horizontal plane. The machine includes at least one resistance mechanism configured to provide resistance against

motion of the foot pedals along their closed loop paths, with the resistance mechanism including an adjustable portion configured to change the magnitude of the resistance provided by the resistance mechanism at a given reciprocation frequency of the foot pedals, and such that the adjustable portion is configured to be readily adjusted by a user of the machine while the user is driving the foot pedals with his feet during exercise.

In some embodiments, the adjustable portion is configured to rapidly adjust between two predetermined resistance settings, such as in less than one second. In some embodiments, the resistance mechanism is configured to provide increased resistance as a function of increased reciprocation frequency of the foot pedals.

In some embodiments, the resistance mechanism includes an air-resistance based resistance mechanism wherein rotation of the air-resistance based resistance mechanism draws air into a lateral air inlet and expels the drawn in air through radial air outlets. The air-resistance based resistance mechanism can include an adjustable air flow regulator that can be adjusted to change the volume of air flow through the air inlet or air outlet at a given rotational velocity of the air-resistance based resistance mechanism. The adjustable air flow regulator can include a rotatable plate positioned at a lateral side of the air-resistance based resistance mechanism and configured to rotate to change a cross-flow area of the air inlet, or the adjustable air flow regulator can include a axially movable plate positioned at a lateral side of the air-resistance based resistance mechanism and configured to move axially to change the volume of air entering the air inlet. The adjustable air flow regulator can be configured to be controlled by an input of a user remote from the air-resistance based resistance mechanism while the user is driving the foot pedals with his feet.

In some embodiments, the resistance mechanism includes a magnetic resistance mechanism that includes a rotatable rotor and a brake caliper, the brake caliper including magnets configured to induce an eddy current in the rotor as the rotor rotates between the magnets, which causes resistance to the rotation of the rotor. The brake caliper can be adjustable to move the magnets to different radial distances away from an axis of rotation of the rotor, such that increasing the radial distance of the magnets from the axis increases the amount of resistance the magnets apply to the rotation of the rotor. The adjustable brake caliper can be configured to be controlled by an input of a user remote from the magnetic resistance mechanism while the user is driving the foot pedals with his feet. Some embodiments of a stationary exercise machine include a stationary frame, first and second reciprocating foot pedals coupled to the frame with each foot pedal configured to move in a respective closed loop path relative to the frame, a crank wheel rotatably mounted to the frame about a crank axis with the foot pedals being coupled to the crank wheel such that reciprocation of the foot pedals about the closed loop paths drives the rotation of the crank wheel, at least one handle pivotally coupled to the frame about a first axis and configured to be driven by a user's hand, wherein the first axis is substantially parallel to and fixed relative to the crank axis. The machine further includes a first linkage fixed relative to the handle and pivotable about the first axis and having a radial end extending opposite the first axis, a second linkage having a first end pivotally coupled to the radial end of the first linkage about a second axis that is substantially parallel to the crank axis, a third linkage that is rotatably coupled to a second end of the second linkage about a third axis that is substantially parallel to the crank

3

axis, wherein the third linkage is fixed relative to the crank wheel and rotatable about the crank axis. The machine is configured such that pivoting motion of the handle is synchronized with motion of one of the foot pedals along its closed loop path.

In some embodiments, the second end of the second linkage includes an annular collar and the third linkage includes a circular disk that is rotatably mounted within the annular collar.

In some embodiments, the third axis passes through the center of the circular disk and the crank axis passes through the circular disk at a location offset from the center of the circular disk but within the annular collar.

In some embodiments, the frame can include inclined members having non-linear portions configured to cause intermediate portions of the lower reciprocating members to move in non-linear paths, such as by causing rollers attached to the intermediate portions of the foot members to roll along the non-linear portions of the inclined members.

Some embodiments of the exercise machine may include a frame including an upper support structure; a crank shaft rotatably coupled with the upper support structure and rotatable about a crank axis; first and second connection members that each rotate about a rotation axis that substantially coincides with the crank axis; first and second crank arms respectively coupled to the first and second connection members to rotate about the rotation axis of its respective connection member; first and second reciprocating foot members operatively associated with the first and second crank arms, respectively, in such a manner that at least a portion of each of the first and second reciprocating foot members orbits the crank shaft as the crank shaft rotates; first and second foot pedals coupled to the first and second reciprocating foot members, respectively; first and second handles supported by the upper support structure to rotate about a handle axis; first and second reciprocating members rotatably coupled to the first and second handles, respectively; and third and fourth connection members operatively associated with the crank shaft and with the first and second connection members, respectively. The third and fourth connection members may each define a rotation axis that is parallel to and offset from the crank axis. The first and second reciprocating members may be rotatably coupled to the third and fourth connection members, respectively, to rotate about the rotation axis defined by its respective connection member.

In some embodiments, the exercise machine may include a first foot member pivot axis defined by the operable association between the first crank arm and the first reciprocating foot member, a second foot member pivot axis defined by the operable association between the second crank arm and the second reciprocating foot member, a first angle formed between a line defined by the crank axis and the first foot member pivot axis and a line defined by the crank axis and the rotation axis formed by the third connection member is greater than 0 degrees and less than 180 degrees, and a second angle formed between a line defined by the crank axis and the second foot member pivot axis and a line defined by the crank axis and the rotation axis formed by the fourth connection member is greater than 0 degrees and less than 180 degrees. The first and second angles may be between approximately 60 degrees and approximately 90 degrees. The first and second angles may be approximately 75 degrees.

In some embodiments, the exercise machine may include at least two spaced-apart plates extending away from the crank axis and each of the plates defining a free end portion,

4

the third connection member positioned between the respective free end portions of each of the plates.

In some embodiments, each rotation axis of the third and fourth connection members may orbit the crank axis as the crank shaft rotates.

Embodiments of the exercise machine may include a frame including an upper support structure; a drive mechanism rotatably coupled with the upper support structure and rotatable about a crank axis; first and second crank arms each engaging the drive mechanism and rotatable about the crank axis; first and second reciprocating foot members operatively associated with first and second crank arms, defining a foot member pivot axis, respectively, wherein the first and second reciprocating foot members are coupled to first and second foot pedals, respectively; and first and second handles operatively associated with first and second reciprocating members. The first and second handles may rotate about a handle axis supported by the upper support structure. The first and second handles may be rotatably coupled to the first and second reciprocating members, respectively, defining a reciprocating axis. The first and second reciprocating members may each be rotatably coupled at a lower end to the drive mechanism and rotatable about an offset axis. Each of the respective offset axes may be parallel to and offset from the crank axis. The first and second crank arms may be fixed to the drive mechanism at respective positions spaced radially inwardly from the offset axes.

In some embodiments, each offset axis may orbit the crank axis as the drive mechanism rotates.

In some embodiments, the drive mechanism may include a central portion, opposing outer end portions, and opposing offset portions positioned between the central portion and each opposing end portion, respectively. The offset portions may extend diametrically from the crank axis. The offset portions may extend away from the crank axis an equal distance. The offset portions may extend away from the crank axis different distances. Each outer end portion may be aligned with the crank axis. Each offset portion may include a pair of spaced-apart plates extending away from the crank axis and each defining free end portions. A shaft may extend between the respective free end portions of the pair of plates. The drive mechanism may be an integral one-piece structure.

In some embodiments, the drive mechanism may include a central portion and opposing offset portions, each of the offset portions including a shaft extending parallel to the crank axis. The lower end of each reciprocating member may rotatably couple to the shaft of one offset portion. The first and second crank arms may each engage an opposing end of the drive mechanism. Each opposing end of the drive mechanism may define an outer end portion. The first and second crank arms may each engage one of the outer end portions.

The foregoing and other objects, features, and advantages of the invention will become more apparent from the following detailed description, which proceeds with reference to the accompanying figures.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a perspective view of an exemplary exercise machine.

FIGS. 2A-2D are left side views of the machine of FIG. 1, showing different stages of a crank cycle.

FIG. 3 is a right side view of the machine of FIG. 1.

5

FIG. 4 is a front view of the machine of FIG. 1. FIG. 4A is an enlarged view of a portion of FIG. 4.

FIG. 5 is a left side view of the machine of FIG. 1. FIG. 5A is an enlarged view of a portion of FIG. 5.

FIG. 6 is a top view of the machine of FIG. 1.

FIG. 7 is a left side view of the machine of FIG. 1.

FIG. 7A is an enlarged view of a portion of FIG. 7, showing closed loop paths traversed by foot pedals of the machine.

FIG. 8 is a right side view of another exemplary exercise machine.

FIG. 9 is a left side view of the machine of FIG. 8.

FIGS. 9A-9F are simplified sectional and full views of FIG. 9 highlighting the input linkages of the example exercise machine.

FIGS. 9G-9N are schematic views stepping through a cycle of the machine relative to various positions of the roller through its range of travel.

FIG. 10 is a front view of the machine of FIG. 8.

FIG. 11 is a perspective view of a magnetic brake of the machine of FIG. 8.

FIG. 12 is a perspective view of an embodiment of the machine of FIG. 8 with an outer housing included.

FIG. 13 is a right side view of the machine of FIG. 12.

FIG. 14 is a left side view of the machine of FIG. 12.

FIG. 15 is a front view of the machine of FIG. 12.

FIG. 16 is a rear view of the machine of FIG. 12.

FIG. 17 is a partial side view of an exemplary exercise machine having curved inclined members taken from FIG. 14.

FIGS. 18A-G are isometric, front, back, left, right, top, and bottom views of an exemplary exercise machine.

FIG. 19 is a perspective view of an exemplary drive member.

FIG. 20 is an enlarged, fragmentary front view of an exemplary embodiment of an exercise machine incorporating the drive member of FIG. 19.

FIG. 21 is an enlarged, fragmentary left side view of the machine of FIG. 20.

FIGS. 22 and 23 are simplified views of the machine of FIG. 20 highlighting the input linkages of the example exercise machine.

DETAILED DESCRIPTION

Described herein are embodiments of stationary exercise machines having reciprocating foot and/or hand members, such as foot pedals that move in a closed loop path. The disclosed machines can provide variable resistance against the reciprocal motion of a user, such as to provide for variable-intensity interval training. Some embodiments can include reciprocating foot pedals that cause a user's feet to move along a closed loop path that is substantially inclined, such that the foot motion simulates a climbing motion more than a flat walking or running motion. Some embodiments can further include upper reciprocating members that are configured to move in coordination with the foot pedals and allow the user to exercise upper body muscles. The resistance to the hand members may be proportional to the resistance to the foot pedals. Variable resistance can be provided via a rotating air-resistance based fan-like mechanism, via a magnetism based eddy current mechanism, via friction based brakes, and/or via other mechanisms, one or more of which can be rapidly adjusted while the user is using the machine to provide variable intensity interval training.

FIGS. 1-7A show an exemplary embodiment of an exercise machine 10. The machine 10 may include a frame 12

6

having a base 14 for contact with a support surface, first and second vertical braces 16 coupled by an arched brace 18, an upper support structure 20 extending above the arched brace 18, and first and second inclined members 22 that extend between the base 14 and the first and second vertical braces 16, respectively.

A crank wheel 24 is fixed to a crankshaft 25 (see FIGS. 4A and 5A) that is rotatably supported by the upper support structure 20 and rotatable about a fixed horizontal crank axis A. First and second crank arms 28 are fixed relative to the crank wheel 24 and crankshaft 25 and positioned on either side of the crank wheel and also rotatable about the crank axis A, such that rotation of the crank arms 28 causes the crankshaft 25 and the crank wheel 24 to rotate about the crank axis A. (Each of the left half and right half of the exercise machine 10 may have similar or identical components, and as discussed herein these similar or identical components may be utilized with the same callout number although opposing components are represented. E.g. crank arms 28 may be located on each side of the machine 10 as illustrated in FIG. 4A). The first and second crank arms 28 have respective first ends fixed to the crankshaft 25 at the crank axis A and second ends that are distal from the first end. The first crank arm 28 extends from its first end to its second end in a radial direction that is opposite the radial direction that the second crank arm extends from its first end and its second end. First and second lower reciprocating members 26 have forward ends that are pivotably coupled to the second ends of the first and second crank arms 28, respectively, and rearward ends that are coupled to first and second foot pedals 32, respectively. First and second rollers 30 are coupled to intermediate portions of the first and second lower reciprocating members 26, respectively, such that the rollers 30 can rollingly translate along the inclined members 22 of the frame 12. In alternative embodiments, other bearing mechanisms can be used to facilitate translational motion of the lower reciprocating members 26 along the inclined members 22 instead of or in addition to the rollers 30, such as sliding friction-type bearings.

When the foot pedals 32 are driven by a user, the intermediate portions of the lower reciprocating members 26 translate in a substantially linear path via the rollers 30 along the inclined members 22. In alternative embodiments, the inclined members 22 can include a non-linear portion, such as a curved or bowed portion (e.g., see the curved inclined members 123 in FIG. 17), such that intermediate portions of the lower reciprocating members 26 translate in non-linear path via the rollers 30 along the non-linear portion of the inclined members 22. The non-linear portion of the inclined members 22 can have any curvature, such as a constant or no constant radius of curvature, and can present convex, concave, and/or partially linear surfaces for the rollers 30 to travel along. In some embodiments, the non-linear portion of the inclined members 22 can have an average angle of inclination of at least 45°, and/or can have a minimum angle of inclination of at least 45°, relative to a horizontal ground plane.

The front ends of the lower reciprocating members 26 can move in circular paths about the rotation axis A, which circular motion drives the crank arms 28 and the crank wheel 24 in a rotational motion. The combination of the circular motion of the forward ends of the lower reciprocating members 26 and the linear or non-linear motion of the intermediate portions of the foot members causes the pedals 32 at the rearward ends of the lower reciprocating members 26 to move in non-circular closed loop paths, such as substantially ovular and/or substantially elliptical closed

loop paths. For example, with reference to FIG. 7A, a point F at the front of the pedals 32 can traverse a path 60 and a point R at the rear of the pedals can traverse a path 62. The closed loop paths traversed by different points on the foot pedals 32 can have different shapes and sizes, such as with the more rearward portions of the pedals 32 traversing longer distances. For example, the path 60 can be shorter and/or narrower than the path 62. A closed loop path traversed by the foot pedals 32 can have a major axis defined by the two points of the path that are furthest apart. The major axis of one or more of the closed loop paths traversed by the pedals 32 can have an angle of inclination closer to vertical than to horizontal, such as at least 45°, at least 50°, at least 55°, at least 60°, at least 65°, at least 70°, at least 75°, at least 80°, and/or at least 85°, relative to a horizontal plane defined by the base 14. To cause such inclination of the closed loop paths of the pedals, the inclined members can include a substantially linear or non-linear portion (e.g., see inclined members 123 in FIG. 17) over which the rollers 30 traverse that forms a large angle of inclination α , an average angle of inclination, and/or a minimum angle of inclination, relative to the horizontal base 14, such as at least 45°, at least 50°, at least 55°, at least 60°, at least 65°, at least 70°, at least 75°, at least 80°, and/or at least 85°. This large angle of inclination of the foot pedal motion can provide a user with a lower body exercise more akin to climbing than to walking or running on a level surface. Such a lower body exercise can be similar to that provided by a traditional stair climbing machine.

The machine 10 can also include first and second handles 34 pivotally coupled to the upper support structure 20 of the frame 12 at a horizontal axis D. Rotation of the handles 34 about the horizontal axis D causes corresponding rotation of the first and second links 38, which are pivotally coupled at their radial ends to first and second upper reciprocating members 40. As shown in FIGS. 4A and 5A, for example, the lower ends of the upper reciprocating members 40 may include respective annular collars 41. A respective circular disk 42 is rotatably mounted within each of the annular collars 41, such that the disks 42 are rotatable relative to the upper reciprocating members 40 and each of the disks' 43 respective collars 41 about respective disk axes B at the center of each of the disks. The disk axes B are parallel to the fixed crank axis A and offset radially in opposite directions from the fixed crank axis A (see FIGS. 4A and 5A). As the crank wheel 24 rotates about the crank axis A, the disk axes B move in opposite circular orbits about the axis A of the same radius. The disks 42 are also fixed to the crankshaft 25 at the crank axis A, such that the disks 42 rotate within the respective annular collars 41 as the disks 42 pivot about the crank axis A on opposite sides of the crank wheel 24. The disks 42 can be fixed relative to the respective crank arms 28, such that they rotate in unison around the crank axis A to crank the crank wheel 24 when the pedals 32 and/or the handles 34 are driven by a user. The handle linkage assembly may include the handles 34, the pivot axis 36, the links 38, the upper reciprocating members 40, and the disks 42. The components may be configured to cause the handles 34 to reciprocate in an opposite motion relative to the pedals 32. For example, as the left pedal 32 is moving upward and forward, the left handle 34 pivots rearward, and vice versa.

The crank wheel 24 can be coupled to one or more resistance mechanisms to provide resistance to the reciprocation motion of the pedals 32 and handles 34. For example, the one or more resistance mechanisms can include an air-resistance based resistance mechanism 50, a magnetism based resistance mechanism, a friction based resistance

mechanism, and/or other resistance mechanisms. One or more of the resistance mechanisms can be adjustable to provide different levels of resistance. Further, one or more of the resistance mechanisms can provide a variable resistance that corresponds to the reciprocation frequency of the exercise machine, such that resistance increases as reciprocation frequency increases.

With reference to FIGS. 1-7, the machine 10 may include an air-resistance based resistance mechanism, such as an air brake 50 that is rotationally mounted to the frame 12. The air brake 50 is driven by the rotation of the crank wheel 24. In the illustrated embodiment, the air brake 50 is driven by a belt or chain 48 that is coupled to a pulley 46, which is further coupled to the crank wheel 24 by another belt or chain 44 that extends around the perimeter of the crank wheel. The pulley 46 can be used as a gearing mechanism to adjust the ratio of the angular velocity of the air brake to the angular velocity of the crank wheel 24. For example, one rotation of the crank wheel 24 can cause several rotations of the air brake 50 to increase the resistance provided by the air brake.

The air brake 50 may include a radial fin structure that causes air to flow through the air brake when it rotates. For example, rotation of the air brake can cause air to enter through lateral openings 52 on the lateral side of the air brake near the rotation axis and exit through radial outlets 54 (see FIGS. 4 and 5). The induced air motion through the air brake 50 causes resistance to the rotation of the crank wheel 24 or other rotating components, which is transferred to resistance to the reciprocation motions of the pedals 32 and handles 34. As the angular velocity of the air brake 50 increases, the resistance force increases in a non-linear relationship, such as a substantially exponential relationship.

In some embodiments, the air brake 50 can be adjustable to control the volume of air flow that is induced to flow through the air brake at a given angular velocity. For example, in some embodiments, the air brake 50 can include a rotationally adjustable inlet plate 53 (see FIG. 5) that can be rotated relative to the air inlets 52 to change the total cross-flow area of the air inlets 52. The inlet plate 53 can have a range of adjustable positions, including a closed position where the inlet plate 53 blocks substantially the entire cross-flow area of the air inlets 52, such that there is no substantial air flow through the fan.

In some embodiments (not shown), an air brake can include an inlet plate that is adjustable in an axial direction (and optionally also in a rotational direction like the inlet plate 53). An axially adjustable inlet plate can be configured to move in a direction parallel to the rotation axis of the air brake. For example, when the inlet plate is further away axially from the air inlet(s), increased air flow volume is permitted, and when the inlet plate is closer axially to the air inlet(s), decreased air flow volume is permitted.

In some embodiments (not shown), an air brake can include an air outlet regulation mechanism that is configured to change the total cross-flow area of the air outlets 54 at the radial perimeter of the air brake, in order to adjust the air flow volume induced through the air brake at a given angular velocity.

In some embodiments, the air brake 50 can include an adjustable air flow regulation mechanism, such as the inlet plate 53 or other mechanism described herein, that can be adjusted rapidly while the machine 10 is being used for exercise. For example, the air brake 50 can include an adjustable air flow regulation mechanism that can be rapidly adjusted by the user while the user is driving the rotation of the air brake, such as by manipulating a manual lever, a

button, or other mechanism positioned within reach of the user's hands while the user is driving the pedals **32** with his feet. Such a mechanism can be mechanically and/or electrically coupled to the air flow regulation mechanism to cause an adjustment of air flow and thus adjust the resistance level. In some embodiments, such a user-caused adjustment can be automated, such as using a button on a console near the handles **34** coupled to a controller and an electrical motor coupled to the air flow regulation mechanism. In other embodiments, such an adjustment mechanism can be entirely manually operated, or a combination of manual and automated. In some embodiments, a user can cause a desired air flow regulation adjustment to be fully enacted in a relatively short time frame, such as within a half-second, within one second, within two seconds, within three second, within four seconds, and/or within five seconds from the time of manual input by the user via an electronic input device or manual actuation of a lever or other mechanical device. These exemplary time periods are for some embodiments, and in other embodiments the resistance adjustment time periods can be smaller or greater.

Embodiments that include a variable resistance mechanism that provide increased resistance at higher angular velocity and a rapid resistance mechanism that allow a user to quickly change the resistance at a given angular velocity allow the machine **10** to be used for high intensity interval training. In an exemplary exercise method, a user can perform repeated intervals alternating between high intensity periods and low intensity periods. High intensity periods can be performed with the adjustable resistance mechanism, such as the air brake **50**, set to a low resistance setting (e.g., with the inlet plate **53** blocking air flow through the air brake **50**). At a low resistance setting, the user can drive the pedals **32** and/or handles **34** at a relatively high reciprocation frequency, which can cause increased energy exertion because, even though there is reduced resistance from the air brake **50**, the user is caused to lift and lower his own body weight a significant distance for each reciprocation, like with a traditional stair climber machine. The rapid climbing motion can lead to an intense energy exertion. Such a high intensity period can last any length of time, such as less than one minute, or less than 30 seconds, while providing sufficient energy exertion as the user desires.

Low intensity periods can be performed with the adjustable resistance mechanism, such as the air brake **50**, set to a high resistance setting (e.g., with the inlet plate **53** allowing maximum air flow through the air brake **50**). At a high resistance setting, the user can be restricted to driving the pedals **32** and/or handles **34** only at relatively low reciprocation frequencies, which can cause reduced energy exertion because, even though there is increased resistance from the air brake **50**, the user does not have to lift and lower his own body weight as often and can therefor conserve energy. The relatively slower climbing motion can provide a rest period between high intensity periods. Such a low intensity period or rest period can last any length of time, such as less than two minutes, or less than about 90 seconds. An exemplary interval training session can include any number of high intensity and low intensity periods, such less than 10 of each and/or less than about 20 minutes total, while providing a total energy exertion that requires significantly longer exercise time, or is not possible, on a traditional stair climber or a traditional elliptical machine.

In accordance with various embodiments, the exercise machine illustrated in FIG. 1-7 may have some differences compared to the machine illustrated in FIGS. 8-11. For example, in FIGS. 1-7 the lower reciprocating members **26**

support the rollers. As shown, the first and second pedals **32** are a contiguous portion of the first and second lower reciprocating members **26**. The first and second lower reciprocating members **26** are each tubular structures with a bend in the tubular structures defining the first and second pedals **32** and with the respective platforms and the respective rollers extending the respective tubular structures forming the first and second pedals. The lower reciprocating member in FIGS. 8-11 attaches directly to a frame **126a** that supports the foot pads **126b**. It is understood that the features of each of the embodiments are applicable to the other.

Referring to FIGS. 8-11, the machine **100** may include a frame **112** having a base **114** for contact with a support surface, a vertical brace **116** extending from the base **114** to an upper support structure **120**, and first and second inclined members **122** that extend between the base **114** and the vertical brace **116**. As reflected in the various embodiments discussed herein, the machine **100** may include an upper moment producing mechanism. The machine may also or alternatively include a lower moment producing mechanism. The upper moment producing mechanism and the lower moment producing mechanism may each provide an input into a crankshaft **125** inducing a tendency for the crankshaft **125** to rotate about axis A. Each mechanism may have a single or multiple separate linkages that produce the moment on the crankshaft **125**. For example, the upper moment-producing mechanism may include one or more upper linkages extending from the handles **134** to the crankshaft **125**. The lower moment-producing mechanism may include one or more lower linkages extending from the pedal **132** to crankshaft **125**. In one example, each machine may have two handles **134** and two linkages connecting each of the handles to the crankshaft **125**. Likewise, the lower moment-producing mechanism may include two pedals and have two linkages connecting each of the two pedals to the crankshaft **125**. The crankshaft **125** may have a first side and a second side rotatable about a crankshaft axis A. The first side and the second side may be fixedly connected to the two upper linkages and/or the two lower linkages, respectively.

In various embodiments, the lower moment-producing mechanism may include a first lower linkage and a second lower linkage corresponding to a left and right side of machine **100**. The first and second lower linkages may include one or more of first and second pedals **132**, first and second rollers **130**, first and second lower reciprocating members **126**, and/or first and second crank arms **128**, respectively. The first and second lower linkages may operably transmit a force input from the user into a moment about the crankshaft **125**.

The machine **100** may include first and/or second crank wheels **124** which may be rotatably supported on opposite sides of the upper support structure **120** about a horizontal rotation axis A. The first and second crank arms **128** are fixed relative to the respective crankshaft **125** which may in turn be fixed relative to the respective first and second crank wheels **124**. The crank arms **128** may be positioned on outer sides of the crank wheels **124**. The crank arms **128** may be rotatable about the rotation axis A, such that rotation of the crank arms **128** causes the crank wheels **124** and/or the crankshaft **125** to rotate. The first and second crank arms **128** extend from central ends at the axis A in opposite radial directions to respective radial ends. For example, the first side and the second side of the crank shaft **125** may be fixedly connected to second ends of first and second lower crank arms. First and second lower reciprocating members **126** have forward ends that are pivotably coupled to the radial ends of the first and second crank arms **128**, respec-

tively, and rearward ends that are coupled to first and second foot pedals **132**, respectively. First and second rollers **130** may be coupled to intermediate portions of the first and second lower reciprocating members **126**, respectively. In various examples, the first and second pedals **132** may each have first ends with first and second rollers **130**, respectively, extending therefrom. Each of the first and second pedals **132** may have second ends with first and second platforms **126b** (or similarly pads), respectively. First and second brackets **126a** may form the portion of the first and second pedals **132** which connects the first and second platforms **132b** and the first and second brackets **132a**. The first and second lower reciprocating members **126** may be fixedly connected to the first and second brackets **126a** between the first and second rollers **130**, respectively, and the first and second platforms **132b**, respectively. The connection may be closer to a front of the first and second platform than the first and second rollers **130**. The first and second platforms **132b** may be operable for a user to stand on and provide an input force. The first and second rollers **130** rotate about individual roller axes T. The first and second rollers may rotate on and travel along first and second inclined members **122**, respectively. The first and second inclined members **122** may form a travel path along the length and height of the first and second incline members. The rollers **130** can rollingly translate along the inclined members **122** of the frame **112**. In alternative embodiments, other bearing mechanisms can be used to provide translational motion of the lower reciprocating members **126** along the inclined members **122** instead of or in addition to the rollers **130**, such as sliding friction-type bearings.

When the foot pedals **132** are driven by a user, the intermediate portions of the lower reciprocating members **126** translate in a substantially linear path via the rollers **130** along the inclined members **122**, and the front ends of the lower reciprocating members **126** move in circular paths about the rotation axis A, which drives the crank arms **128** and the crank wheels **124** in a rotational motion about axis A. The combination of the circular motion of the forward ends of the lower reciprocating members **126** and the linear motion of the intermediate portions of the foot members causes the pedals **132** at the rearward ends of the foot members to move in non-circular closed loop paths, such as substantially ovular and/or substantially elliptical closed loop paths. The closed loop paths traversed by the pedals **132** can be substantially similar to those described with reference to the pedals **32** of the machine **10**. A closed loop path traversed by the foot pedals **132** can have a major axis defined by the two points of the path that are furthest apart. The major axis of one or more of the closed loop paths traversed by the pedals **132** can have an angle of inclination closer to vertical than to horizontal, such as at least 45°, at least 50°, at least 55°, at least 60°, at least 65°, at least 70°, at least 75°, at least 80°, and/or at least 85°, relative to a horizontal plane defined by the base **114**. To cause such inclination of the closed loop paths of the pedals **132**, the inclined members **122** can include a substantially linear portion over which the rollers **130** traverse. The inclined members **122** form a large angle of inclination a relative to the horizontal base **114**, such as at least 45°, at least 50°, at least 55°, at least 60°, at least 65°, at least 70°, at least 75°, at least 80°, and/or at least 85°. This large angle of inclination which sets the path for the foot pedal motion can provide the user with a lower body exercise more akin to climbing than to walking or running on a level surface. Such a lower body exercise can be similar to that provided by a traditional stair climbing machine.

In various embodiments, the upper moment-producing mechanism **90** may include a first upper linkage and a second upper linkage corresponding to a left and right side of machine **100**. The first and second upper linkages may include one or more of first and second handles **134**, first and second links **138**, first and second upper reciprocating members **140**, and/or first and second virtual crank arms **142a**, respectively. The first and second upper linkages may operably transmit a force input from the user, at the handles **134**, into a moment about the crankshaft **125**.

With reference to FIGS. **8-10**, the first and second handles **134** may be pivotally coupled to the upper support structure **120** of the frame **112** at a horizontal axis D. Rotation of the handles **134** about the horizontal axis D causes corresponding rotation of first and second links **138**, which are pivotally coupled at their radial ends to first and second upper reciprocating members **140**. The first and second links **138** and the handle **134** may be pivotable about the D axis. For example, the first and second links **138** may be cantilevered off of handles **134** at the pivot aligned with the D axis. Each of the first and second links **138** may have angle ω with the respective handles **134**. The angle may be measured from a plane passing through the axis D and the curve in the handle proximate the connection to the link **138**. The angle ω may be any angle such as angles between 0 and 180 degrees. The angle ω may be optimized to one that is most comfortable to a single user or an average user. The lower ends of the upper reciprocating members **140** may pivotably connect to the first and second virtual crank arms **142a**, respectively. The first and second virtual crank arms **142a** may be rotatable relative to the rest of the upper reciprocating members **140** about respective axes B (which may be referred to as virtual crank arm axes). Axes B may be parallel to the crank axis A. Each axis B may be located proximal to an end of each of the upper reciprocating members **140**. Each axis B may also be located proximal to one end of the virtual crank arm **142a**. Each axis B may be offset radially in opposite directions from the axis A. Each respective virtual crank arm **142a** may be perpendicular to axis A and each of the axes B, respectively. The distance between axis A and each axis B may define approximately the length of the virtual crank arm. This distance between axis A and each axis B is also the length of the moment arm of each virtual crank arm **142a** which exerts a moment on the crankshaft. As used herein, the virtual crank arm **142a** may be any device which exerts a moment on the crankshaft **125**. For example, as used above the virtual crank arm **142a** may be the disk **142**. In another example, the virtual crank arm **142a** may be a crank arm similar to crank arm **128**. Each of the virtual crank arms may be a single length of semi-ridged to ridged material having pivots proximal to each end with one of the reciprocating members pivotably connected along axis B proximal to one end and the crankshaft fixedly connected along axis A proximally connected to the other end. The virtual crank arm may include more than two pivots and have any shape. As discussed hereafter, the virtual crank arm is described as being disk **142** but this is merely as an example, as the virtual crank arm may take any form operable to apply a moment to crankshaft **125**. As such, each embodiment including the disk may also include the virtual crank arm or any other embodiment disk herein or would be understood by one of ordinary skill in the art as applicable.

In the embodiment in which the vertical crank arm **142a** is the rotatable disk **142**, the structure of the upper reciprocating members **140** and rotatable disks **142** should be understood to be similar to the upper reciprocating members **40** and disks **42** of the machine **10**, as shown in FIG. **3-7**.

13

However any of the virtual crank arms, crank arms, disks or the like may also be applicable to the embodiments of FIG. 3-7. The lower ends of the upper reciprocating members 140 may be positioned just inside of the crank wheels 124, as shown in FIG. 10. As the crank wheels 124 rotate about the axis A, the disk axes B orbits about the axis A. The disks 142 are also pivotably coupled to the crank axis A, such that the disks 142 rotate within the respective lower ends of the upper reciprocating members 140 as the disks 142 pivot about the crank axis A on opposite sides of the upper support member 120. The disks 142 can be fixed relative to the respective crank arms 128, such that they rotate in unison around the crank axis A to crank the crank wheel 124 when the pedals 132 and/or the handles 134 are driven by a user.

The first and second links 138 may have additional pivots coaxial with axis C. The upper reciprocating members 140 may be connected to the links 138 at the pivot coaxial with axis C. As indicated above, the upper reciprocating members 140 may be connected with the annular collars 141. Annular collar 141 encompasses rotatable disk 142 with the two being able to rotate independent of one another. As the handles 134 articulate back and forth they move links 138 in an arc, which in turn articulates the upper reciprocating members 140. Via the fixed connection between the upper reciprocating member 140 and annular collar 141, the articulation of handle 134 also moves annular collar 141. As rotatable disk 142 is fixedly connected to and rotatable around the crankshaft which pivots about axis A, rotatable disk 142 also rotates about axis A. As the upper reciprocating member 140 articulates back and forth it forces the annular collar 141 toward and away from the axis A along a circular path with the result of causing axis B and/or the center of disk 142 to circularly orbit around axis A.

In accordance with various embodiments, the first linkage 90 may be an eccentric linkage. As illustrated in FIG. 9E, the upper reciprocating member 140 drives the eccentric wheel which includes the annular collar 141 and the disk 142. With the disk rotating around axis A as the fixed pivot, the disk center axis B travels around A in a circular path. This path is possible because of the freedom of relative rotational movement between the annular collar 141 and the disk 142. The distance between axis A and axis B is operable as the rotating arm of the linkage. As shown in the diagram illustrated in FIG. 9E, a force F1 is applied to the upper reciprocating member 140. For example, the force may be in the direction shown or opposite the direction shown. If in the direction shown by F1, the upper reciprocating member 140 and the annular collar 141 place a load on disk 142 through axis B. However, as disk 142 is fixed relative to crankshaft 125, which is rotatable around axis A, the load on disk 142 causes a torque to be placed on the crankshaft 125, which is coaxial with axis A. As the force F1 is sufficient to overcome the resistance in crankshaft 125, the disk 142 begins to rotate in direction R1 and the crankshaft begins to rotate in direction R2. With F1 in the opposite direction, R1 and R2 would likewise be in the opposite direction. As illustrated by FIG. 9F, as the cycle continues for the eccentric linkage, the force F1 must change directions in order to continue driving rotation in the direction R1, R2 of the disk 142 and crankshaft 125 respectively.

In accordance with various embodiments, the second mechanical advantage is produced by the combination of components within the second linkage 92. Within the second linkage 92, the pedals 132 pivot around the first and second rollers 30 in response to force being exerted against the first and second lower reciprocating members 126 through the pedals 132. The force on the first and second lower recip-

14

rocating members 126 drives the first and second crank arms 128 respectively. The crank arms 128 are pivotably connected at axes E to the first and second lower reciprocating members 126 and fixedly connected to the crankshaft 125 at axis A. As the first and second lower reciprocating members 126 are articulated, the force (e.g. F2 shown in FIGS. 9E, 9F) drives the crank arms 128, which rotate the crankshaft 125 about axis A. FIGS. 9B, 9C, and 9D each show the pedals 132 in different positions with corresponding different positions in the crank arms 128. These corresponding different positions in the crank arms 128 also represent rotation of the crankshaft 125 which is fixedly attached to the crank arms 128. Due to the fixed attachment, the crank arms 128 can transmit input to the crankshaft 125 that the crank arms 128 receive from the first and second lower reciprocating members 126. The crank arms 128 may be fixedly positioned relative to disk 142. As discussed above, the disk 142 may have a virtual crank arm 142a which is the portion of the disk 142 extending approximately perpendicular to and between axis B and axis A.

As shown in FIG. 9E, the virtual crank arm 142a may be set at an angle of λ from the angle of the crank arm 128 (i.e. the component extending approximately perpendicular to and between axis A and Axis E.) As the disk 142 and the crank arm 128 rotate, for example 90 degrees, the crank arm 128 may stay at the same relative angle to the virtual crank arm 142a. The angle λ may be between any angle (i.e. 0-360 degrees). In one example, the angle λ may be between 60° and 90°. In one example, the angle λ may be 75°.

Understanding this exemplary embodiment of linkages 90 and 92, it may be understood that the mechanical advantage of the linkages may be manipulated by altering the characteristics of the various elements. For example, in first linkage 90, the leverage applied by the handles 134 may be established by length of the handles or the location from which the handles 134 receive the input from the user. The leverage applied by the first and second links 138 may be established by the distance from axis D to axis C. The leverage applied by the eccentric linkage may be established by the distance between axis B and axis A. The upper reciprocating member 140 may connect the first and second links 138 to the eccentric linkage (disk 142 and annular collar 141) over the distance from axis C to axis B. The ratio of the distance between axes D and C compared to the distance between axis B and A (i.e. D-C:B-A) may be in one example, between 1:4 and 4:1. In another example, the ratio may be between 1:1 and 4:1. In another example, the ratio may be between 2:1 and 3:1. In another example, the ratio may be about 2.8:1. In one example, the distance from axis D to axis C may be about 103 mm and the distance from axis B to axis A may be about 35 mm. This defines a ratio of about 2.9:1. Similar ratios may apply to the ratio of axis B to axis A compared to axis A to axis E (i.e. B-A:A-E). In various examples, the distance from axis A to axis E may be about 132 mm. In various examples, the distance from either of axes E to one of the respective axes T (i.e. one of the axes around which the roller rotates) is about 683 mm. The distance from E to T may be represented by X as shown in FIG. 9B. While X generally follows the length of the lower reciprocating member, it may be noted as discussed herein that the lower reciprocating member 126 may not be a straight connecting member but may be multiple portions or multiple members with one or more bends occurring intermediately therein as illustrated in FIG. 8, for example.

With reference to FIGS. 9A-9F, the handles 134 provide an input into the crankshaft 125 through the upper linkage. The pedals 132 provide an input into the crankshaft wheel

15

125 through a second linkage 92. The crankshaft being fixedly connected to the crank wheel 124 causes the two to rotate together relative to each other.

Each handle may have a linkage assembly, including the handle 134, the pivot axis D, the link 138, the upper reciprocating member 140, and the disk 142. Two handle linkage assemblies may provide input into the crankshaft 125. Each handle linkage may be connected to the crankshaft 125 relative to the pedal linkage assembly such that each of the handles 134 reciprocates in an opposite motion relative to the pedals 132. For example, as the left pedal 132 is moving upward and forward, the left handle 134 pivots rearward, and vice versa.

The upper moment-producing mechanism 90 and the lower moment-producing mechanism 92, functioning together or separately, transmit input by the user at the handles to a rotational movement of the crankshaft 125. In accordance with various embodiments, the upper moment-producing mechanism 90 drives the crankshaft 125 with a first mechanical advantage (e.g. as a comparison of the input force to the moment at the crankshaft). The first mechanical advantage may vary throughout the cycling of the handles 134. For example, as the first and second handles 134 reciprocate back and forth around axis D through the cycle of the machine, the mechanical advantage supplied by the upper moment-producing mechanism 90 to the crankshaft 125 may change with the progression of the cycle of the machine. The upper moment-producing mechanism 90 drives the crankshaft 125 with a second mechanical advantage (e.g. as a comparison of the input force at the pedals to the torque at the crankshaft at a particular instant or angle). The second mechanical advantage may vary throughout the cycle of the pedals as defined by the vertical position of the rollers 130 relative to their top vertical and bottom vertical position. For example, as the pedals 132 change position, the mechanical advantage supplied by the lower moment-producing mechanism 92 may change with the changing position of the pedals 132. The various mechanical advantage profiles may rise to a maximum mechanical advantage for the respective moment-producing mechanisms at certain points in the cycle and may fall to minimum mechanical advantages at other points in the cycle. In this respect, each of the moment-producing mechanisms 90, 92 may have a mechanical advantage profile that describes the mechanical effect across the entire cycle of the handles or pedals. The first mechanical advantage profile may be different than the second mechanical advantage profile at any instance in the cycle and/or the profiles may generally be different across the entire cycle. The exercise machine 100 may be configured to balance the user's upper body workout (e.g. at the handles) by utilizing the first mechanical advantage differently as compared to the user's lower body workout (e.g. at the pedals 132) utilizing the second mechanical advantage. In various embodiments, the upper moment-producing mechanism 90 may substantially match the lower moment-producing mechanism 92 at such points where the respective

16

mechanical advantage profiles are near their respective maximums. Regardless of difference or similarities in respective mechanical advantage profiles throughout the cycling of the exercise machine, the inputs to the handles and pedals still work in concert through their respective mechanisms to drive the crankshaft 125.

One example of the structure and characteristics of the exercise machine is provided in the table below and reflected in FIGS. 9G-N. The table represents an embodiment as described below and analyzed as a single linkage such as on one half of a machine (e.g. the left linkage of an exercise machine). The force applied to the handle or the handle force and the force applied to the pedal or the pedal force is shown by arrow F and each of the forces is equal forces. The handle force is applied at a distance about 376 mm from the axis D which locates the force at a position about the middle of the handle grip that a user may typically use. The pedal force is applied to the foot pad at a distance of about 381 mm from the axis T which locates the force at a position about the middle of the foot pad where a user may typically stand. The length from axis D to axis C is about 104 mm. The length from axis B to axis A is about 35 mm. The length from axis A to axis E is about 132 mm. The length from axis E to axis T is about 683 mm. The angle between the member that extends between axis B to axis A and the member that extends between axis A and axis E is about 75°. The exercise machine may include an individual cycle as defined by a full reciprocation of one of the handles, a full rotation of the crankshaft, a full loop of one of the foot pedals, or any other criteria that would indicate a full repetition of the components of the exercise machine. Column 1 below identifies a step in the cycle so as to identify the locations, ranges, and/or changing values of the other attributes in the table. Column 2 identifies positions of the handles relative to the other attributes in the table. Column 3 identifies positions of the roller axis relative to the other attributes in the table. Column 4 identifies the positions of the crankshaft relative to the other attributes as measured from a vertical plane passing through axis A; the angles are measured from 0 to 180° on a first half of the cycle as defined by the crankshaft angle and from -180 to 0° on the second half of the cycle as defined the crankshaft angle. Column 5 identifies the angle between the component that extends between axis D and axis C and the component that extends between axis B and axis C relative to the point in the cycle. Column 6 identifies the angle between the component that extends between axis C and axis B and the component that extends between axis A and axis B relative to the point in the cycle. Column 7 identifies the angle between the component that extends between axis A and axis E and the component that extends between axis T and axis E relative to the point in the cycle. Column 8 identifies the approximate mechanical advantage ratio relative to the point in the cycle. The mechanical advantage ratio is equal to the mechanical advantage in lower moment-producing mechanism 92 divided by the mechanical advantage in the upper moment-producing mechanism 90.

In accordance with various embodiments, the rollers may travel along the incline members from a bottom position to a top position and back down. The full round trip of the rollers may account for a cycle of the exercise machine. As shown in FIGS. 9G-9N, the rollers may have vertical positions along the incline member as indicated by RP1, RP2, RP3, RP4, and RP5. RP1 corresponds to the top vertical position of the roller also reflected in the table above. RP2 corresponds to the top middle vertical position of the roller also reflected in the table above. RP3 corresponds to the middle vertical position of the roller also reflected in the table above. RP4 corresponds to the bottom middle vertical position of the roller also reflected in the table above. RP5 corresponds to the bottom vertical position of the roller also reflected in the table above. During a single cycle, the roller may be positioned at RP2, RP3, and RP4 each twice, once on the way down and once on the way up, thus forming eight example positions. Each of these positions may also be accounted for by crankshaft angle as measured off the vertical and also relative position of the handle as shown in the table above. It may be noted that an infinite number of positions exist in each cycle, but these positions are shown as mere examples.

The power band of the cycle may be defined as the range in the cycle of the exercise machine in which the moment-producing mechanisms (e.g. upper moment-producing mechanism 90 and lower moment-producing mechanism 92) obtain their respective maximum mechanical advantages. Stated another way, the moment-producing mechanisms are outside of their respective dead zones, the dead zones being the range of the cycle in which the moment goes to zero. In these dead zones, the ratio between the upper moment-producing mechanism 90 and lower moment-producing mechanism 92 decreases in its usefulness as the ratio may approach zero or infinity. Each cycle may have a plurality of power bands. The cycle may have one power band, two power bands, three power bands, four power bands, or more. For example, if there are four different linkages (e.g. two upper linkages and two lower linkages) and each linkage has two dead zones different from the other linkages, in a cycle there may be eight power bands existing between each of those dead zones. In another example, if there are four different linkages (e.g. two upper linkages and two lower linkages) and the dead zones of some linkages are

the same (e.g. the upper linkages are the same and the lower linkages are the same) and the dead zones of the opposing linkages (e.g. upper linkages versus lower linkages) are different but still close together, then there may not be a power band between the dead zones of the opposing linkages. Linkages on opposite sides of the machine (e.g. left versus right side) may have identical mechanical advantage profiles but be 180 degrees out of phase, thus having dead zones at the same time but from different parts of the cycle.

In accordance with one example, the table and FIGS. 9G-9N show an example of two linkages from the same side of an exercise machine. The exercise machine may have an angular power band between 0° and 110° in one half of the cycle and 155° to 180° and -180° to -70° in the other half of the cycle as defined by the angle of the crankshaft beginning with the crank arm in a vertical position. The converse of this is that the dead zones may exist from 110° to 155° and -70° to 0° of the crankshaft. These power bands for the cycle may be similarly described in terms of roller vertical position or handle position. For example, the exercise machine may have a power band as defined by the roller from the upper middle roller position (e.g. RP2) to the lower middle roller position (e.g. RP4). In another example, the exercise machine may have a power band as defined by the handle from the forward middle handle position to the rear middle handle position.

In accordance with various embodiments, the upper moment-producing mechanism 90 and the lower moment-producing mechanism 92 provide a mechanical advantage ratio of between about 0.6 and 1.4 in a power band of the cycle as defined by roller position. In various examples, the upper moment-producing mechanism 90 and the lower moment-producing mechanism 92 provide a mechanical advantage ratio of between about 0.8 and 1.1 in response to the roller being located at its midpoint of vertical travel during the cycle.

In accordance with various embodiments, the lower moment-producing mechanism 92 (e.g. the first and second lower linkages) may produce a maximum mechanical advantage on the crankshaft in response to being in a power band of the cycle. In accordance with various embodiments, the upper moment-producing mechanism 90 (e.g. first and second upper linkages) may produce a maximum mechanical advantage on the crankshaft in response to being in a power band of the cycle.

In accordance with various embodiments, the angle between the component (e.g. the upper links **138**) that extends between axis D and axis C and the component (e.g. the upper reciprocating links **140**) that extends between axis B and axis C may be from about 70° to 115° throughout the cycle. In various examples, this angle may be between 80° and 100° in response to the first and second handles being proximate to the midpoint of their travel. In various examples, this angle may be between about 80° and 105° in response to the respective first and second rollers being at about the midpoint of their travel which is approximately the location in which the lower linkage has maximum mechanical advantage on the crankshaft. In various examples, this angle may be between 80° and 100° in response to the exercise machine being within the power band of its cycle.

The angle between the component (e.g. the upper reciprocating member) that extends between axis C and axis B and the component (e.g. the virtual crank arm) that extends between axis A and axis B may be from about 0° to 180° throughout the cycle. In various examples, this angle may be between 65° and 115° in response to at least one of the respective first and second rollers being at about the midpoint of their travel, the first and second lower linkages producing a maximum mechanical advantage on the crankshaft, the first and second handles being proximate to the midpoint of their travel, or the exercise machine being within the power band of its cycle.

The angle between the component (e.g. the crank arm) that extends between axis A and axis E and the component (e.g. the lower reciprocating member) that extends between axis T and axis E may be from -20° to 165° throughout the cycle. In various examples, this angle may be between 80° and 100° in response to at least one of the respective first and second rollers being at about the midpoint of their travel, the first and second lower linkages producing a maximum mechanical advantage on the crankshaft, the first and second handles being proximate to the midpoint of their travel, or the exercise machine being within the power band of its cycle. As shown in FIG. 10, the machine **100** can further include a user interface **102** mounted near the top of the upper support member **120**. The user interface **102** can include a display to provide information to the user, and can include user inputs to allow the user to enter information and to adjust settings of the machine, such as to adjust the resistance. The machine **100** can further include stationary handles **104** mounted near the top of the upper support member **120**.

The resistance mechanisms as variously discussed herein may be operatively connected to the crankshaft **125** such that the resistance mechanism resists the combined moments provided at the crankshaft from the upper moment-producing mechanism **90** and the lower moment-producing mechanism **92**. The crank wheels **124** can be coupled to one or more resistance mechanisms directly or through the crankshaft **125** to provide resistance to the reciprocation motion of the pedals **132** and handles **134**. For example, the one or more resistance mechanisms can include an air-resistance based resistance mechanism **150**, a magnetism based resistance mechanism **160**, a friction based resistance mechanism, and/or other resistance mechanisms. One or more of the resistance mechanisms can be adjustable to provide different levels of resistance at a given reciprocation frequency. Further, one or more of the resistance mechanisms can provide a variable resistance that corresponds to the reciprocation frequency of the exercise machine, such that resistance increases as reciprocation frequency increases.

As shown in FIGS. 8-10, the machine **100** can include an air-resistance based resistance mechanism, or air brake, **150** that is rotationally mounted to the frame **112** on an horizontal shaft **166**, and/or a magnetism based resistance mechanism, or magnetic brake, **160**, which includes a rotor **161** rotationally mounted to the frame **112** on the same horizontal shaft **166** and brake caliper **162** also mounted to the frame **112**. The air brake **150** and rotor **161** are driven by the rotation of the crank wheels **124**. In the illustrated embodiment, the shaft **166** is driven by a belt or chain **148** that is coupled to a pulley **146**. Pulley **146** is coupled to another pulley **125** mounted coaxially with the axis A by another belt or chain **144**. The pulleys **125** and **146** can be used as a gearing mechanism to set the ratio of the angular velocity of the air brake **150** and the rotor **161** relative to the reciprocation frequency of the pedals **132** and handles **134**. For example, one reciprocation of the pedals **132** can cause several rotations of the air brake **150** and rotor **161** to increase the resistance provided by the air brake **150** and/or the magnetic brake **160**.

The air brake **150** can be similar in structure and function to the air brake **50** of the machine **10** and can be similarly adjustable to control the volume of air flow that is induced to flow through the air brake at a given angular velocity.

The magnetic brake **160** provides resistance by magnetically inducing eddy currents in the rotor **161** as the rotor rotates. As shown in FIG. 11, the brake caliper **162** includes high power magnets **164** positioned on opposite sides of the rotor **161**. As the rotor **161** rotates between the magnets **164**, the magnetic fields created by the magnets induce eddy currents in the rotor, producing resistance to the rotation of the rotor. The magnitude of the resistance to rotation of the rotor can increase as a function of the angular velocity of the rotor, such that higher resistance is provided at high reciprocation frequencies of the pedals **132** and handles **134**. The magnitude of resistance provided by the magnetic brake **160** can also be a function of the radial distance from the magnets **164** to the rotation axis of the shaft **166**. As this radius increases, the linear velocity of the portion of the rotor **161** passing between the magnets **164** increases at any given angular velocity of the rotor, as the linear velocity at a point on the rotor is a product of the angular velocity of the rotor and the radius of that point from the rotation axis. In some embodiments, the brake caliper **162** can be pivotably mounted, or otherwise adjustable mounted, to the frame **116** such that the radial position of the magnets **164** relative to the axis of the shaft **166** can be adjusted. For example, the machine **100** can include a motor coupled to the brake caliper **162** that is configured to move the magnets **164** to different radial positions relative to the rotor **161**. As the magnets **164** are adjusted radially inwardly, the linear velocity of the portion of the rotor **161** passing between the magnets decreases, at a given angular velocity of the rotor, thereby decreasing the resistance provided by the magnetic brake **160** at a given reciprocation frequency of the pedals **132** and handles **134**. Conversely, as the magnets **164** are adjusted radially outwardly, the linear velocity of the portion of the rotor **161** passing between the magnets increases, at a given angular velocity of the rotor, thereby increasing the resistance provided by the magnetic brake **160** at a given reciprocation frequency of the pedals **132** and handles **134**.

In some embodiments, the brake caliper **162** can be adjusted rapidly while the machine **10** is being used for exercise to adjust the resistance. For example, the radial position of the magnets **164** of the brake caliper **162** relative to the rotor **161** can be rapidly adjusted by the user while the user is driving the reciprocation of the pedals **132** and/or

handles **134**, such as by manipulating a manual lever, a button, or other mechanism positioned within reach of the user's hands, illustrated in FIG. **10**, while the user is driving the pedals **132** with his feet. Such an adjustment mechanism can be mechanically and/or electrically coupled to the magnetic brake **160** to cause an adjustment of eddy currents in the rotor and thus adjust the magnetic resistance level. The user interface **102** can include a display to provide information to the user, and can include user inputs to allow the user to enter to adjust settings of the machine, such as to adjust the resistance. In some embodiments, such a user-caused adjustment can be automated, such as using a button on the user interface **102** that is electrically coupled to a controller and an electrical motor coupled to the brake caliper **162**. In other embodiments, such an adjustment mechanism can be entirely manually operated, or a combination of manual and automated. In some embodiments, a user can cause a desired magnetic resistance adjustment to be fully enacted in a relatively short time frame, such as within a half-second, within one second, within two seconds, within three second, within four seconds, and/or within five seconds from the time of manual input by the user via an electronic input device or manual actuation of a mechanical device. In other embodiments, the magnetic resistance adjustment time periods can be smaller or greater than the exemplary time periods provided above.

FIGS. **12-16** show an embodiment of the exercise machine **100** with an outer housing **170** mounted around a front portion of the machine. The housing **170** can house and protect portions of the frame **112**, the pulleys **125** and **146**, the belts or chains **144** and **148**, lower portions of the upper reciprocating members **140**, the air brake **150**, the magnetic brake **160**, motors for adjusting the air brake and/or magnetic brake, wiring, and/or other components of the machine **100**. As shown in FIGS. **12**, **14**, and **15** the housing **170** can include an air brake enclosure **172** that includes lateral inlet openings **176** to allow air into the air brake **150** and radial outlet openings **174** to allow air out of the air brake. As shown in FIGS. **13** and **15**, the housing **170** can further include a magnetic brake enclosure **176** to protect the magnetic brake **160**, where the magnetic brake is included in addition to or instead of the air brake **150**. The crank arms **128** and crank wheels **124** can be exposed through the housing such that the lower reciprocating members **126** can drive them in a circular motion about the axis A without obstruction by the housing **170**.

FIGS. **18A-G** illustrate various views of one example of the exercise machine. In the example shown in FIGS. **18A-G**, the exercise machine may be a generally upright device that occupies a small amount of floor space due to the generally vertical nature of the machine as a whole. As respectively shown, FIGS. **18A-G** depict an example isometric, front, back, left, right, top, and bottom view of the exercise machine. Each of these views also depicts ornamental aspects of the exercise machine.

A further embodiment of the exercise machine **310** is shown in FIGS. **19** through **23**. Many of the structural features and functions are the same or similar to those shown and described with respect to embodiments described herein, including with respect to FIGS. **1** through **7**, and with respect to FIGS. **8**, **9A**, **9B** and **10**. Common elements between the embodiments may be referenced by the same or different name and by the same or different reference number.

In this further embodiment, and referring to FIGS. **19** through **21**, a drive mechanism **180** operatively associates and inter-engages the upper moment-producing mechanism

390 and the lower moment-producing mechanism **392** to create a respective first and second mechanical advantage similar to or the same as the described herein with respect to the embodiment shown in FIGS. **8**, **9A**, **9B**, and **10**. The drive mechanism **180** of this further embodiment allows for the same or similar application of rotational moment to the crank axis as described in various other embodiments herein. In this further embodiment, the virtual crank arms **142a** are formed by an eccentric mechanism formed by the certain elements of the drive mechanism **180**.

Referring specifically to FIG. **19**, the drive mechanism **180** is a longitudinally extending structure made from suitable materials, such as metal or the like, and defines a plurality of sections or portions along its length. The drive mechanism **180** may include a central portion or crank shaft **182**, first and second outer end portions **184**, **188**, and first and second offset portions **192**, **196**. For increased strength, the drive mechanism **180** may be monolithically formed as an integral one-piece structure in some embodiments. The first outer end portion **184** may include a first connection member **186**, and the second outer end portion **188** may include a second connection member **190**. The first offset portion **192** may include a third connection member **194** defining a rotation axis. The third connection member **194** is operatively associated with the crank shaft **182** and the first connection member **186**, and in one example is positioned between the first outer end portion **184** and the crank shaft **182**. The second offset portion **196** may include a fourth connection member **198** defining a rotation axis. The second offset portion **196** is operatively associated with the crank shaft **182** and the second connection member **190**, and in another example is positioned between the second outer end portion **188** and the crank shaft **182**. At least part of the length of the crank shaft **182** is linear such that when rotated it defines a rotational axis or a crank axis. The outer end portions **184**, **188** are at least partially linear, and aligned with the central portion **182** such that when rotated, each of the first and second connection members **186**, **190** rotate about and define a rotation axis that coincides with the crank axis, including aligning coextensively with the crank axis.

With continued reference to FIG. **19**, each of the first and second offset portions **192**, **196** may be attached to the crank shaft **182**. In one example, each of the first and second offset portions **192**, **196** may extend away from the crank axis (e.g., diametrically from the crank axis) such that the rotation axis defined by each of the third and fourth connection members **194**, **198** is parallel to and offset from the crank axis. In some embodiments, the first and second offset portions **192**, **196** may extend away from the crank axis an equal distance, or in some examples may extend away from the crank axis different distances depending on the desired characteristics of the drive mechanism **180**. Additionally, each offset portion **192**, **196** may include an inner plate **210** spaced apart from an outer plate **212**. Each inner plate **210** extends radially away from the crank axis with a proximal end fixed to an end of the central portion **182** and a distal end **214** coupled to its respective connection member **194**, **198**, the distal end **214** being considered a free end portion. Each outer plate **212** extends radially away from the crank axis with a proximal end fixed to an end of a respective outer end portion **184**, **188**, and a distal end **216** coupled to its respective connection member **194**, **198**, the distal end **216** being considered a free end portion. Each third and fourth connection member **194**, **198** extends between and is fixed (such as by press-fitting or welding) to the distal ends **214**, **216** of each of its respective inner **210** and outer **212** plates. Each third and fourth connection member **194**, **198** is spaced

away from (the same or different distances) and may extend parallel with the crank axis, and in one example is circular in cross section along part of its length. Each third and fourth connection member **194, 198** may take the form of a shaft or the like that in part forms a bearing surface **220** around which a component is rotatably coupled, and through which a rotational axis extends. Each pair of plates **210, 212** may be positioned parallel or non-parallel to one another, and may extend orthogonally or non-orthogonally relative to the crank axis. The plate members **210, 212** may be similarly shaped to one another, or may have different shapes. The various components of the drive mechanism **180** described above may be secured together in a manner to create an integrally-formed one-piece structure having sufficient strength to resist bending forces applied along its length, whether or not through the crank axis. In one example of an alternative embodiment, the offset portions **192, 196** may include longitudinal extensions of the central portion **182** bent to form offset portions **192, 196** defining a bearing surface **220** spaced away from and extending parallel to the crank axis, and bent to form the outer end portions **184, 188**. Such an alternative may provide a cost benefit in producing the drive mechanism **180**. The drive mechanism **180** utilizing plates **210, 212** for the offset portions **192, 196** may be more expensive to produce because of the number of parts and required assembly steps, but provide a likely stronger structure with more efficient spacing and a tighter tolerance for rotational alignment, resulting in an overall shorter and higher-quality drive mechanism **180**.

The upper moment-producing mechanism **390** of FIGS. **19** and **20** may include a first upper linkage and/or a second upper linkage corresponding to a left and right side of machine **310**. The first and second upper linkages may include one or more of first and second handles **334**, and/or first and second upper reciprocating members **340**, respectively. The first and second upper linkages are operably associated with the drive mechanism **180**, and operably transmit a force input by the user's movement of one or both of the handles **334** to the drive mechanism **180**, and create a moment force about a crank axis (also referred to herein as crank axis A), which creates the first mechanical advantage. The first and second linkages may be eccentric linkages as noted below.

In more detail, and with continuing reference to FIGS. **19** and **20**, the first and second handles **334** may be supported by the upper support structure **320** of the frame **312** and rotate about a handle axis, for example axis D. The first and second handles **334** are rotatably coupled to the first and second reciprocating members **340**, respectively. In one example, a first portion of each of the reciprocating members **340**, such as an end portion, is operably associated with a connection portion **338** of a corresponding handle **334**, such as by a pivotal connection, so as to be rotatably coupled to the respective handle **334**. Each of the reciprocating members **340** rotates relative to the connection portion **338** of the respective handle **334** about a reciprocating axis, similar to or the same as axes C described herein. Rotation of the handles **334** about the handle axis D causes corresponding rotation of each of the connection portions **338** (one on each handle **334**) about the handle axis D. The connection portion **338** of each handle **334** to which the first portion of each reciprocating member is respectively attached may be a lever or extension member extending away from the handle **334**, allowing the reciprocating axis to be positioned along the length of the lever members and be spaced away from the handle axis D. In this instance, when the handles **334** are rotated about the handle axis D, each reciprocating axis (and

the first portion of each reciprocating member **340**) moves about the handle axis D, such as in an orbital or circumferential manner. Each of the lever members may define more than one position for the respective reciprocating axis, allowing the adjustment of the radial location of each of the reciprocating axes relative to the handle axis D, and thus the length and curvature of the arc defined by the movement of each reciprocating axis (see FIG. **21**). This in turn affects the length and curvature of the arc through which the first end of each reciprocating member **340** moves. Where the connection portions **338** are lever members, each lever member forms an angle ω with the respective handles, as described elsewhere herein.

Referring still to FIGS. **19** and **20**, second portions of the upper reciprocating members **340**, such as second end portions opposite the first end portions, are rotatably coupled, such as by a pivot or journaled connection, to the first and second offset portions **192, 196**, respectively, forming first and second respective rotation axes, such axes being the same or similar to axes B described elsewhere herein. Each of the first and second rotation axes B may be offset radially from the crank axis A, and may be parallel to the crank axis A. The first and second rotation axes B may be spaced away from the crank axis A in radially opposite directions, or in radial directions defining an angle of less than 180 degrees. Each rotation axis B may be located proximal to an end of each of the upper reciprocating members **340**. Each rotation axis B may also be located proximal to a free end **214, 216** of the offset portion **192, 196**. Each rotation axis B may also be referred to herein as an offset axis B. Each respective offset portion **192, 196** may be perpendicular to the crank axis A and each of the rotation axes B, respectively. The distance between the crank axis A and each of the rotational axes B may define approximately the length of the offset portion **192, 196**. The offset portions **192, 196** are each an embodiment of the virtual crank arm, for example such as virtual crank arm **142a**, as described herein.

As indicated above, the first and second reciprocating members **340** may be rotatably coupled to the third and fourth connection members **194, 198**, respectively, to rotate about the rotation axis B defined by its respective connection member **194, 198**. In one example, the second ends of each of the upper reciprocating members **340** may be rotatably coupled with respective offset portions **192, 196** to allow relative movement about the respective rotation axis B. As the handles **334** articulate back and forth about the handle axis D, the first end of each respective reciprocating member **340** operably associated with the connection portion **338** of each respective handle **334** moves, such as through an arc where the connection portion **338** is defined on a lever member, which in turn articulates the upper reciprocating members **340**. The movement of the first end of each upper reciprocating member **340** applies a moving force to the respective rotation axis B formed at the engagement between the second end of the reciprocating member **340** and the offset portion **192, 196**. As each offset portion **192, 196** is fixedly connected to and rotatable with the crank shaft **182** about the crank axis A, each rotation axis B and offset portion **192, 196** also rotate about axis A. Because a rotational force is applied to the crank shaft **182** through one or both of the rotation axes B, and the rotational axes B are offset from the crank axis A (e.g. eccentric to the crank axis), the first linkage may be considered an eccentric linkage. Thus, as each of the upper reciprocating members **340** articulate back and forth, each biases the respective eccentric rotation axis B to at least partially rotate about, and at least

partially orbit, the crank axis A. This relative motion applies a moment to the crank shaft **182** to rotate about the crank axis A.

Each offset portion **192**, **196** and the adjacent crank arm **328** extend from different sections of the drive mechanism **180** and form an angle λ with its vertex located on the crank shaft **182**. This angle λ is similar to or the same as the angle λ described with respect to the earlier embodiments related to FIGS. 7-10, and may range between 0 and 360 degrees, and may also be more preferably between approximately 60 and approximately 90 degrees, and in one example may preferably be 75 degrees. The structural difference in this further embodiment is that a discrete link between the rotation axis B and the crank axis A as compared to the disk **42** and outer collar **41** assembly used in the earlier embodiments.

In this further embodiment, with continuing reference to FIGS. 19-21, and in the same or similar manner described with respect to the other embodiments described herein, the lower moment-producing mechanism **392** may include a first lower linkage and a second lower linkage corresponding to a left and right side of machine **310**. The first and second lower linkages may include one or more of first and second rollers **330**, first and second lower reciprocating members **326** (also referred to as "foot members"), first and second pedals **332** coupled to the first and second reciprocating foot members **26**, and/or first and second crank arms **328**, respectively. The first and second lower linkages may operably transmit a force input from the user into a moment about the crank shaft **182**. The first and second crank arms **328** are each coupled at a first end portion, such as by being fixedly attached, to first and second connection members **186**, **190**, respectively, of the drive mechanism **180**. Each of the first and second crank arms **328** rotate about the rotation axis of the respective connection member **186**, **190** to which it is attached. The crank arms **28** may extend in opposite radial directions from the drive mechanism **180**. Movement of either or both of the crank arms **328** causes rotation of the drive mechanism **180**, with the crank arms **328** and drive mechanism **180** rotating about the crank axis A. Each of the first and second crank arms **328** is operatively associated with respective reciprocating foot members **326** such that at least a portion of each of the first and second reciprocating foot members **326** orbits the crank axis A as the drive mechanism **180** rotates. In one example the second end portions of each crank arm **328** are pivotally attached at a first end portion of each reciprocating foot member **326** and each define a foot member pivot axis, such axis being the same or similar to axis E described elsewhere herein.

In accordance with various embodiments, and with reference to FIGS. 22 and 23, the first linkage may be an eccentric linkage. As illustrated in FIG. 22, the upper reciprocating member **340** drives the offset portion **192**. With the offset portion **192** rotating around the crank axis A, which is a fixed pivot, the rotational axis (offset axis B) formed on the, for example, third connection member **194** travels around (e.g. orbits) crank axis A in a circular path as the crank shaft **182** rotates. The distance between crank axis A and rotational axis (offset axis B) is operable as the rotating arm of the linkage. As shown in the diagram illustrated in FIG. 22, a force F1 is applied to the upper reciprocating member **340**. For example, the force F1 may be in the direction shown or opposite the direction shown. If in the direction shown by F1, the upper reciprocating member **340** and the offset member **192** place a load or torque on crank shaft **182**, which is rotatable around axis A. As the force F1 is sufficient to overcome the resistance

against rotation in crank shaft **182**, the offset portion **192** begins to rotate in direction R1 and the drive mechanism **180** begins to rotate in direction R2. With F1 in the opposite direction, R1 and R2 would likewise be in the opposite direction. As illustrated by FIG. 23, as the cycle continues for the eccentric linkage, the force F1 must change directions in order to continue driving rotation in the direction R1, R2 of the offset portion **192** and the crank shaft **182**, respectively. As is described elsewhere herein, the angle λ between the crank shaft **182** and the link formed by the offset member **192** remains constant.

For purposes of this description, certain aspects, advantages, and novel features of the embodiments of this disclosure are described herein. The disclosed methods, apparatuses, and systems should not be construed as limiting in any way. Instead, the present disclosure is directed toward all novel and nonobvious features and aspects of the various disclosed embodiments, alone and in various combinations and sub-combinations with one another. The methods, apparatuses, and systems are not limited to any specific aspect or feature or combination thereof, nor do the disclosed embodiments require that any one or more specific advantages be present or problems be solved.

As used herein, the terms "a", "an" and "at least one" encompass one or more of the specified element. That is, if two of a particular element are present, one of these elements is also present and thus "an" element is present. The terms "a plurality of" and "plural" mean two or more of the specified element.

As used herein, the term "and/or" used between the last two of a list of elements means any one or more of the listed elements. For example, the phrase "A, B, and/or C" means "A," "B," "C," "A and B," "A and C," "B and C" or "A, B and C."

All relative and directional references (including: upper, lower, upward, downward, left, right, leftward, rightward, top, bottom, side, above, below, front, middle, back, vertical, horizontal, height, depth, width, and so forth) are given by way of example to aid the reader's understanding of the particular embodiments described herein. They should not be read to be requirements or limitations, particularly as to the position, orientation, or use of the invention unless specifically set forth in the claims. Connection references (e.g., attached, coupled, connected, joined, and the like) are to be construed broadly and may include intermediate members between a connection of elements and relative movement between elements. As such, connection references do not necessarily infer that two elements are directly connected and in fixed relation to each other, unless specifically set forth in the claims.

Unless otherwise indicated, all numbers expressing properties, sizes, percentages, measurements, distances, ratios, and so forth, as used in the specification or claims are to be understood as being modified by the term "about." Accordingly, unless otherwise indicated, implicitly or explicitly, the numerical parameters set forth are approximations that may depend on the desired properties sought and/or limits of detection under standard test conditions/methods. When directly and explicitly distinguishing embodiments from discussed prior art, numbers are not approximations unless the word "about" is recited.

In view of the many possible embodiments to which the principles disclosed herein may be applied, it should be recognized that the illustrated embodiments are only examples and should not be taken as limiting the scope of the disclosure. Rather, the scope of the disclosure is at least as broad as the following exemplary claims.

27

The invention claimed is:

1. A stationary exercise machine, comprising:
 - a frame including an upper support structure;
 - a crank shaft rotatably coupled with the upper support structure and rotatable about a crank axis;
 - first and second connection members that each rotate about a rotation axis that substantially coincides with the crank axis;
 - first and second crank arms coupled to the first and second connection members, respectively, to rotate about the rotation axis of its respective connection member;
 - first and second reciprocating foot members operatively associated with the first and second crank arms, respectively, in such a manner that at least a portion of each of the first and second reciprocating foot members orbits the crank shaft as the crank shaft rotates;
 - first and second foot pedals coupled to the first and second reciprocating foot members, respectively;
 - first and second handles supported by the upper support structure to rotate about a handle axis;
 - a first reciprocating member rotatably coupled to an end of the first handle, and a second reciprocating member rotatably coupled to an end of the second handle;
 - third and fourth connection members operatively associated with the crank shaft and with the first and second connection members, respectively;
 - the third and fourth connection members each define a rotation axis that is parallel to and offset from the crank axis; and
 - the first and second reciprocating members rotatably coupled to the third and fourth connection members, respectively, to rotate about the rotation axis defined by its respective connection member.
2. A stationary exercise machine comprising:
 - a frame including an upper support structure;
 - a crank shaft rotatably coupled with the upper support structure and rotatable about a crank axis;
 - first and second connection members that each rotate about a rotation axis that substantially coincides with the crank axis;
 - first and second crank arms coupled to the first and second connection members, respectively, to rotate about the rotation axis of its respective connection member;
 - first and second reciprocating foot members operatively associated with the first and second crank arms, respectively, in such a manner that at least a portion of each of the first and second reciprocating foot members orbits the crank shaft as the crank shaft rotates;
 - first and second foot pedals coupled to the first and second reciprocating foot members, respectively;
 - first and second handles supported by the upper support structure to rotate about a handle axis;
 - first and second reciprocating members rotatably coupled to the first and second handles, respectively;
 - third and fourth connection members operatively associated with the crank shaft and with the first and second connection members, respectively;
 - the third and fourth connection members each define a rotation axis that is parallel to and offset from the crank axis;
 - the first and second reciprocating members rotatably coupled to the third and fourth connection members, respectively, to rotate about the rotation axis defined by its respective connection member;
 - a first foot member pivot axis defined by the operable association between the first crank arm and the first reciprocating foot member and a second foot member

28

- pivot axis defined by the operable association between the second crank arm and the second reciprocating foot member;
 - a first angle formed between a line defined by the crank axis and the first foot member pivot axis and a line defined by the crank axis and the rotation axis formed by the third connection member is greater than 0 degrees and less than 180 degrees; and
 - a second angle formed between a line defined by the crank axis and the second foot member pivot axis and a line defined by the crank axis and the rotation axis formed by the fourth connection member is greater than 0 degrees and less than 180 degrees.
3. The stationary exercise machine as defined in claim 2, wherein the first and second angles are between approximately 60 degrees and approximately 90 degrees.
 4. The stationary exercise machine as defined in claim 3, wherein the first and second angles are approximately 75 degrees.
 5. The stationary exercise machine as defined in claim 1, further comprising:
 - at least two spaced-apart plates extending away from the crank axis and each of the plates defining a free end portion; and
 - the third connection member positioned between the respective free end portions of each of the plates.
 6. The stationary exercise machine as defined in claim 1, wherein each rotation axis of the third and fourth connection members orbits the crank axis as the crank shaft rotates.
 7. A stationary exercise machine, comprising:
 - a frame including an upper support structure;
 - a drive mechanism rotatably coupled with the upper support structure and rotatable about a crank axis;
 - first and second crank arms each engaging the drive mechanism and rotatable about the crank axis;
 - first and second reciprocating foot members operatively associated with the first and second crank arms, defining a foot member pivot axis, respectively, wherein the first and second reciprocating foot members are coupled to first and second foot pedals, respectively;
 - first and second handles operatively associated with first and second reciprocating members, wherein:
 - the first and second handles rotate about a handle axis supported by the upper support structure;
 - the first and second handles are rotatably coupled to the first and second reciprocating members, respectively, defining a reciprocating axis;
 - the first and second reciprocating members are each rotatably coupled at a lower end to the drive mechanism and rotatable about an offset axis;
 - each of the respective offset axes is parallel to and offset from the crank axis; and wherein
 - the first and second crank arms are fixed to the drive mechanism at respective positions spaced radially inwardly from the offset axes.
 8. A stationary exercise machine as defined in claim 7, wherein each offset axis orbits the crank axis as the drive mechanism rotates.
 9. The stationary exercise machine as defined in claim 7, wherein the drive mechanism includes a central portion, opposing outer end portions, and opposing offset portions positioned between the central portion and each opposing end portion, respectively.
 10. The stationary exercise machine as defined in claim 9, wherein the offset portions extend diametrically from the crank axis.

29

11. The stationary exercise machine as defined in claim **9**, wherein the offset portions extend away from the crank axis an equal distance.

12. The stationary exercise machine as defined in claim **9**, wherein the offset portions extend away from the crank axis 5 different distances.

13. The stationary exercise machine as defined in claim **9**, wherein each outer end portion is aligned with the crank axis.

14. The stationary exercise machine as defined in claim **9**, 10 wherein:

each offset portion includes a pair of spaced-apart plates extending away from the crank axis and each defining free end portions; and

a shaft extends between the respective free end portions of 15 the pair of plates.

15. The stationary exercise machine as defined in claim **9**, wherein the drive mechanism is an integral one-piece structure.

16. The stationary exercise machine as defined in claim **7**, 20 wherein:

30

the drive mechanism includes a central portion and opposing offset portions; and each of the offset portions includes a shaft extending parallel to the crank axis.

17. The stationary exercise machine as defined in claim **16**, wherein the lower end of each reciprocating member rotatably couples to the shaft of one offset portion.

18. The stationary exercise machine as defined in claim **17**, wherein the first and second crank arms each engage an 10 opposing end of the drive mechanism.

19. The stationary exercise machine as defined in claim **18**, wherein:

each opposing end of the drive mechanism defines an outer end portion; and

the first and second crank arms each engage one of the 15 outer end portions.

20. The stationary exercise machine as defined in claim **1**, wherein the first and second foot pedals are coupled to first and second ends of the first and second reciprocating foot 20 members, respectively.
